Treatment of Injuries of the Liver.—In penetrating wounds the existing wound can be enlarged and converted as far as possible into the incisions about to be described. If the site of injury is in the left lobe, or is undetermined, a median incision should be made; in wounds of the right lobe a curved incision along the lower border of the costal cartilages and to the right of the rectus muscle is to be preferred. In some cases these may be combined, thus forming an angular incision. Since by far the greater number of wounds of the liver are located on the ventral or lateral aspects of the viscus, these two plans of attack will nearly always suffice. In wounds situated posteriorly, the lumbar incision is hardly to be recommended on account of the thickness of the muscular walls, and the fact should be borne in mind that, as reported by Lannelongue, the thoracic wall can be resected along the anterior portions of the eighth, ninth, tenth, and eleventh costal cartilages, for the pleura does not extend down to this part of the chest wall. The method of Lannelongue consists in an incision parallel with the thoracic border and two centimetres above the same, beginning three centimetres from the border of the sternum and ending at the junction of the tenth rib with the costal cartilage. The retraction of the divided muscles exposes the costal cartilages to be resected; they are carefully freed from their attachments and cut through with cartilage scissors. Then, if the ends of the ribs are retracted and pressed apart, nearly the entire extent of the convexity of the liver can be made accessible.—SCHLATTER.

Capital Operations without Anæsthesia.—1. Patients with limbs so crushed as to require amputation, who are in good general condition, should be operated on at once. 2. Those who present evidences of severe shock and great loss of blood, should be treated by external heat and stimulants, including the hypodermatic use of whiskey, digitalin, strychnine, and nitroglycerin, and the rectal injection of whiskey, strong coffee, and hot water. The crushed limb should be disinfected as completely as possible, and 6 to 1,000 saline solution of not less than two quarts for an adult be allowed to flow into a vein, this infusion to be repeated, if necessary, at intervals of a few hours, according to the effect produced. 3. If by these efforts complete reaction should be established, anæsthesia and amputation should be proceeded with as in ordinary cases. 4. If, however, a moderate or doubtful reaction only should occur, the propriety of a rapid amputation without anæsthesia should be seriously considered, if the consent of the patient be gained. 5. The complete disinfection of crushed, lacerated, dirty, and infected limbs usually cannot be accomplished. 6. The sooner such limbs are removed, the better, provided the patient's life be not lost in the operation. 7. If, notwithstanding the vigorous treatment just mentioned, an amputation, either with or without anæsthesia, be fraught with great risk, it is far better to disinfect as thoroughly as possible, drain well, pack all open spaces, and take the chance of infection, which in most doubtful cases is probably less than the risk of death from shock following operation.—BUCHANAN.

Treatment of Tuberculous Cavities.—Equal parts of iodoform and calomel form a harmless and powerful antiseptic dressing for the cavities left after operating for tuberculosis of the bones, joints, tracheotomies, etc. It promotes the formation of a thin eschar, thus preventing the sticking of the dressings to the tissues. After hæmostasis is secured, the powder is sprinkled over the walls of the cavity with a small pointed spoon and rubbed in with a gauze pad held in the forceps. As much as four and one-half grams can thus be applied without inconvenience. The wound is afterward kept open with a tampon.—SPRENGEL, *Chl. f. Chir.*, February 6th.

Remote Effects of Bone Trauma.—The practical propositions involved in this paper are based on inflammation or irritation in bone following injury and the sequel resulting therefrom. 1. Resolution, including a complete restoration of the bone to its normal condition, occurs in the vast majority of cases. 2. Resulting in rarefying ostitis. Condensing ostitis, or a combined rarefying and condensing ostitis, which may remain as a more or less permanent condition: if slight in degree, giving rise to no well-marked subjective or objective signs after the process becomes arrested. 3. If the process continues for a period beyond a few months, well-marked and unmistakable changes in the physical condition and appearance of the bone will become manifest. 4. A persistent acute or chronic osteomyelitis will also give rise to unmistakable physical changes in the bone. 5. A persistent chronic osteo-periostitis will give rise to thickening of both periosteum and bone of a character that will be readily recognized if the bone is so situated as to admit of easy surface examination. 6. If the products of inflammation in cases of rarefying ostitis or in osteomyelitis become infected with pus-forming microbes, the suppurative process will become plainly evident, except in cases in which the process is very limited, giving rise to a small abscess in the bone which may be indicated only by subjective symptoms. 7. The injury and irritation following may establish a *locus minoris resistentiæ*, which may become the seat of tuberculous infection with certain definite results. The length of time after a trauma during which this influence may exist cannot be definitely determined, but it may be assumed in the light of critical practical experience and pathological research that the special predisposition will cease to exist as soon as the effused blood is absorbed, and the protoplasmic elements—the products of irritation or inflammation—have been resolved into new bone or have undergone degeneration and absorption, *i.e.*, as soon as the normal nutrition balance is restored. I do not believe there is any scientific evidence or any practical facts that will bear criticism, which will support the assumption that the *locus minoris resistentiæ* may continue for months or years after all signs of the injury and its immediate results have disappeared. 8. There is no evidence to show that a carcinoma or sarcoma may develop as the result of an injury after the immature bone elements have become transformed into tissue of a normal resisting physiological type.—DR. D. S. FAIRCHILD, *Journal of the American Medical Association*, July 10th.

Irreducible Hernia.—From the facts and arguments adduced the following conclusions were drawn: 1. That irreducible hernia is a condition of serious danger, the gravity of which increases with its duration or neglect. 2. That the application of a truss upon an irreducible hernia is not only useless, but harmful. 3. That irreducible herniæ which consist wholly or in part of bowel are very apt to become strangulated. 4. That herniæ consisting wholly of bowel, upon which no truss has been worn, may (even when of large size and of considerable duration) generally be returned by appropriate treatment. 5. That of the cases of hernia in which proper treatment fails to obtain reduction, the great majority are irreducible because of adhesions of, or changes in, the protruded

viscera—conditions which are remediable only by operation. 6. That the most common cause of irreducibility is the presence in the sac of adherent omentum. 7. That the presence of irreducible omentum in the sac of a hernia is a source of constant danger, which can, nevertheless, be remedied by an operation of extremely small risk. 8. That herniæ containing irreducible bowel are more dangerous than those containing only omentum, and that as the danger of operation increases with the magnitude of the hernia and with the occurrence of adhesions, these herniæ should be operated upon as soon as they are proved by the failure of proper treatment to be irreducible.—Dr. Warrington Howard, meeting of the Royal Medical and Chirurgical Society, May 26th.

Nævi.—Mixed nævi and venous nævi, unless they are adapted for excision, are best treated by electrolysis; and this electrolysis should be done very patiently, a little at a time, with a long interval between each use of the needles, to get the full effect of the shrinking of the growth; it is impossible to hurry the process, and in the end one gets the best results by working slowly. Capillary nævi, if they ulcerate, are generally to be left to themselves; this natural cure of them will probably give as good a scar as we should get by the use of caustics.—Dr. Paget, *The Clinical Journal*, April 28th.

Correspondence.

OUR LONDON LETTER.

[From our Special Correspondent.]

PARLIAMENT: UNIVERSITY BILL, ARMY MEDICAL SERVICE, RABIES, ETC.—COLLEGE OF PHYSICIANS AND HOSPITAL ABUSE—THE REFORM ASSOCIATION—BRITISH MEDICAL ASSOCIATION—EXPULSION OF MEMBERS—SUNDAY FUND—MORTUARIES—THE GLASGOW CHAIR OF MATERIA MEDICA.

[London, August 1, 1897.]

Both houses of Parliament met this morning to close the session, and members are now released for their holidays. There has not been much done during the week. The London Universities bill has been slaughtered with other innocents, but the government proposes to introduce it next session. If it means to pass it they must bring it forward earlier and submit it to further discussion than is possible at a late period. The army medical service has given rise to several questions in the Commons. It was admitted that thirty-six vacancies were declared and only twenty-eight candidates applied, two of whom were medically unfit, three did not appear, and one was otherwise disqualified. Further questions elicited that for the Indian medical service there were eighteen vacancies for which thirty-eight candidates applied, but five of these were physically unfit. The contrast beween these two sets of figures should surely open the eyes of the government to its folly in supporting the prejudices of the "military advisers" in wrecking the service; if not the country will soon be demanding a change in unmistakable terms. The difficulty of obtaining leave to which medical officers are entitled by the regulations was also brought forward and excuses were made on account of the home establishment being under strength—but whose fault is it that the service is undermanned? Rabies, muzzling dogs, glanders, and the late water famine in East London were also subjects of questions.

The Royal College of Physicians, as I have already informed you, has expressed its inability to undertake a thorough examination of the question of hospital abuse. But the Reform Association is not discouraged. Rather is it determined to continue to agitate the question. At the dinner of the association last week Mr. Timothy Holmes was present. He worked at this question when it was agitated in 1871, but I cannot see any change for the better since then; in fact, the evil has extended and is a blight on the profession. The Hospital Sunday Fund has had no good influence in this direction. Rather has its tendency been in the contrary direction and its management must be reformed. Its rule as to the relation of maintenance and administration is calculated to stimulate reckless expenditure, and its officials assume an infallibility and assert their views in terms discourteous and offensive. A change is urgently called for.

The Mercers' Hospital dispute seems to be extending its area. The governors hold that they removed Mr. O'Grady from the surgeoncy by their resolution dismissing the whole staff. But Mr. O'Grady denies their authority and is prepared to appeal to the courts. Meantime, being himself a governor, he could not be prevented from visiting the hospital and holding himself out as surgeon to it. The next move was a motion "that the board dispense with the services of Mr. O'Grady as governor." Whether governors can thus remove one of their number who demands reforms opens a still wider question.

The expulsion of the two members of the British Medical Association for accepting posts in the Adelaide Hospital is causing some searchings of hearts. It is true the membership confers no advantage beyond receiving the journal and admission to the meetings, and the members expelled may therefore afford to laugh at the solemnity assumed by the ruling clique. There is, however, another aspect of the matter. If the stigma of expulsion is to be placed on women for taking posts in the colonies vacated by others in defence of the honor of the profession, how about the men in London who have eagerly grasped appointments in precisely similar circumstances? Are they too numerous to attack? Is it not notorious that the *Journal* has basely deserted the men fighting in such a case and even supported their supplanters? Perhaps after the criticism on the editor's conduct at the meeting here such scandals may not be repeated. But to return to the expulsion. If this is to be a precedent, it would be interesting to learn whether any of the new staff of Mercers' Hospital are members of the Association, and further whether any of the numerous candidates for those appointments are also members. And further, if so, are they to be arraigned and if not why not?

We have it now on the authority of the chairman of the county council that arrangements have been made which will obviate the necessity of holding inquests in public houses, good mortuary accommodation having been provided in nearly all the London districts. Such mortuaries are increasingly used for the reception of corpses awaiting interment in other than inquest cases. The public is recognizing the advantage of removing corpses from crowded houses to properly arranged mortuaries in which sentiment is respected and sanitation satisfied. The extension of the mortuary system is therefore a fact on which London and its authorities are to be congratulated.

An exhibition was held last week of medical and hygienic articles. It seems to have been designed to take the place of the museum of the British Medical Association, and the exhibits were much the same as those annually shown at the meetings.

Dr. Stockman succeeds the late Dr. Charteris as professor of materia medica and therapeutics at the University of Glasgow.

OUR VIENNA LETTER.

(From our Special Correspondent.)

VACATION COURSES DURING SEPTEMBER—KOCH'S NEW TUBERCULIN—REPORTS AS TO ITS THERAPEUTIC VALUE NOT ENCOURAGING—THE AUSTRIAN BOARD OF HEALTH AND MEASURES AGAINST THE PLAGUE—MOSCOW AND ACCOMMODATIONS FOR MEMBERS OF THE CONGRESS—SOME DISSATISFACTION WITH PRICES DEMANDED FOR RESERVED ROOMS.

VIENNA, July 30, 1897.

THE vacation courses open here on Monday August 2d, the programme for them having been out for some time. The giving of a series of regular courses during the vacations was tried more or less as an experiment last year. The result was so satisfactory that now these courses are to be made a special feature of the medical work here. The announcements for September especially show that an effort is to be made to rival in Vienna the Berlin vacation courses, which for years now have attracted a large international attendance. American visitors to the international congress at Moscow will have an opportunity on their way home to see the methods of the Vienna school and get an idea of medical life here notwithstanding that it is vacation time.

Professor Koch's new serum was not received very enthusiastically by the profession here, and observations made with it do not seem to confirm even the limited claims that its inventor now makes for it. The Vienna school has always been much more interested in pathology than in therapeutics, and new remedies generally are received very coolly and tried in a conservative scientific way that usually reduces considerably the enthusiastic claims of the discoverer. Even when Koch's tuberculin first came out and the whole medical world became so completely wrapped up in the demonstration of the effectiveness of the new remedy, Vienna went on in the even tenor of its way and calmly awaited developments. That from various sources there should come unfavorable reports as to the action of the tuberculin, even when supplied directly by the commercial house to which Koch has intrusted its preparation, is not surprising, for most observations made with it even in Germany have not been distinctly favorable; while from other countries the reports would seem to be distinctly unfavorable.

From a series of cases reported here it is clear that gradually an immunity against the action of the tuberculin itself is acquired, and that large doses of it may then be borne without any consequent febrile reaction. This does not include protection against the tubercle bacillus itself, however, or its products. Even when the patient under treatment fails to react to the tuberculin, bacilli may be found in his sputum and the area of dulness in his lungs may be demonstrated to be increasing in size. In some cases during the treatment bacilli have disappeared from the sputum, but in no case in which an area of dulness in the lungs could be demonstrated has that been found to diminish in size. On the other hand, patients who had been gaining in weight before they began the treatment, *i.e.*, with only the ordinary constitutional hygienic and dietetic measures, have been known to lose in weight after the injections were commenced. This opinion as to the doubtful value of the new tuberculin seems to be shared by most of the clinicians here who have tried the new remedy, and they are not few in number. That it will be of certain usefulness in the early diagnosis of doubtful cases seems to be generally admitted, but therapeutically it is more than likely to share the fate of its predecessor in the same field and after exploitation for a time be allowed to drop out of use.

One of the surprising reports about it, considering the well-known thoroughness of its inventor in such matters, is that the preparation is not always sterile. A number of slight abscesses and interstitial exudations that were sore for some days having followed its use, cultures were taken from a number of samples and pus micro-organisms were sometimes found to be present. This is probably due to the fact that the preparation is put up in wooden-stoppered bottles, for continental use at least; that these become soaked with moisture from the underlying serum, and so form an excellent culture ground for micro-organisms. It is a bit of mechanical imperfection, an oversight that one would scarcely expect under the circumstances, however, and that will often prove annoying in its consequences to the practitioner.

Though the Austrian plague commission's official report declared that the plague was not under ordinary circumstances very contagious and that the infection was not liable to be carried in fomites, the Austrian health authorities consider it advisable to take certain special precautions against its possible introduction. Professor Weichselbaum has been asked in his official capacity as state medical counsellor to furnish the government physicians with the data and the material necessary to insure the prompt bacteriological recognition of the disease should suspicious cases occur. He has been asked too to open a course at the Pathological Institute in which the characteristics of the bacillus will be minutely described and specimens and cultures of it shown, so that its observation may be a matter of practical experience.

Austria has at best but a limited seacoast, though that of course is in dangerous communication with the East through the Mediterranean. The additional precautions seemingly are taken not so much because there seems from a scientific standpoint any liability of the introduction of the plague as because public opinion demands some practical application of the governmental investigation of the disease. Money for purely scientific purposes is not usually voted willingly and some return must be shown for the expense incurred. The Austrian commission's report as to the non-contagion through fomites has been formally confirmed by the German commission with Koch at its head, which finds that the bacillus is incapable of growing after it has been eight days outside the body. As has been often pointed out before, the only real danger that may exist is in the possibility of rats on shipboard, the animals being very liable to the disease and being probably the great infection carriers in the epidemics that occur.

The tickets for members of the congress at Moscow, together with the railroad tickets that are to carry them free from the Russian border to Moscow and back, are at last reaching their destinations. The doctors are to travel practically as government officials and the privileges accorded are ample. Notifications of the reservation of rooms for those who wrote to the secretary for that purpose are also at hand. These are not so satisfactory as the railroad tickets, and a good many in Vienna seem to be of the opinion that there will be some exploitation of visitors by hotel people—that in fact there will be a repetition of some of the unpleasantness experienced at Rome during the last International Medical Congress. Moscow is of course much larger than Rome; the last Russian census taken last year gives it about 900,000 population, and one might reasonably conclude that 7,000 visitors (that is the number of free railroad tickets issued) would easily find accommodations without the possibility of crowding. Moscow's floating population, however, is very small; in the matter of hotels she is decidedly provincial, and so her capacity for the reception of visitors is probably to be tested to its utmost limit. It is to

be hoped that some of the presentiments in the matter of discomfort and expense that are now rather freely expressed may not be realized. The committee of arrangements has shown so far its thorough ability to cope with the various and at times vexing problems that arose, and it may be confidently depended on to put the finishing touches to its work in arranging for the convenience of its guests.

New Instruments.

URINATING-TUBE FOR USE WITH WOUNDS OF THE PERINEUM.

By J. G. CROSS, M.S., M.D.,

ROCHESTER, MINN.

THE instrument herewith presented to the profession was devised for use with female patients with surgical or traumatic wounds of the perineum not yet healed, neccessitating urination while in the recumbent position. It consists simply of a conducting tube of annealed glass, so fashioned that its upper end fits the

parts about the meatus urinarius without pressing upon the urethra, and by a suitable curve avoids contact with the perineum, but carries the urine into the receptacle below. The illustration makes further description unnecessary.

The advantages of this tube over the catheter in the class of cases mentioned are readily seen. It is easily rendered sterile, being entirely of smooth glass, annealed to withstand heat. Its use gives the patient no discomfort, and requires no especial skill in the attendant. The urine is kept entirely away from the wound, even the drop that usually follows the withdrawal of a catheter from the urethra. With simple directions as to cleanliness, it can be safely left in hands to which the physician would hesitate to intrust the care and use of a catheter.

The urinating-tubes are made by Tiemann & Co., of New York.

The Future of Greek and Turk.—In the preface to his "Impressions of Turkey during Twelve Years' Wanderings," recently published by the Putnams, Prof. W. M. Ramsay says that he was strongly impressed with one great contrast between the average Turkish and Greek villages. In Turkish villages the women, so far as he could judge from sight and report, are feebler and poorer in both physique and mind (owing to their hard lot in childhood); whereas the Greek women struck him as being better and morally higher than the men, physically good, and intellectually well developed. Therein he believes lies the future of the two races. In the one case there is a rich soil from which future generations acquire strength and moral vigor; in the other a stunted and impoverished motherhood produces a poor and diminishing people. "In the condition of the Turkish women lies the reason for the steady degeneration of the Turkish people."

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending August 14, 1897:

	Cases.	Deaths.
Tuberculosis	155	105
Typhoid fever	52	9
Scarlet fever	81	3
Cerebro-spinal meningitis	1	1
Measles	79	5
Diphtheria	157	27
Laryngeal diphtheria (croup)	1	0
Chicken-pox	4	0

The Healing of Wounds in the Negro Races.—Dr. Plehn (*Deutsche med. Woch.*, 34, 1896) says that infected wounds are rare among the negro races in Africa, and that severe wounds heal sooner than do like wounds in Europeans. He is of the opinion that specific pus organisms are not common in Kamerun or that the tissues of the negro are resistant.

Gluttony has its victims, hardly less numerous than other vices. To overeat is to overburden the digestive organs to such an extent that it will be impossible for them to perform their duties properly, deleterious products are created, and health is finally destroyed. No man can overeat and live out his expectancy. It is as important to inquire into the habits of a man proposed for insurance in this respect as in drinking. Men have been known to kill themselves in this manner. A prominent judge in New Jersey used to say such men dig their graves with their teeth—and it is so.—*The Medical Examiner.*

Water Purification.—Dr. Thomas B. Carpenter concludes an article on this subject (*Albany Medical Annals*, April, 1897) as follows: 1. Purification of water should be municipal, not domestic, because domestic filtration cannot be relied upon. 2. Domestic purification can be best obtained by heating to 80° C. for twenty minutes. 3. All evidence available at the present time favors the superiority of "natural" filtration for purification on a large scale. 4. With few exceptions, all American cities furnish their inhabitants a water that is at least suspicious, and in most cases polluted. 5. A continued typhoid mortality of over twenty per one hundred thousand means a polluted water and a preventable sacrifice of human life.

"Charaka-Samhita."—Part sixteen of the translation of this curious Hindu medical classic closes the section on the pathogenesis of disease and on timely and untimely death, and takes up that on diagnosis. The three especial means for ascertaining the nature of disease are the following of the instructions of the inspired, observation, and inference. The matters about which the inspired lay down instructions, the matters which are apprehended by observation, and the matters which are to be ascertained by inference, and the manner in which they are to be known, are here fully expounded in this lesson. The closing section treats of the several ducts of the body, their contents, and the symptoms pointing to disease of them.

Vital Statistics of Philadelphia.—For the week ending July 31st there were reported to the Philadelphia board of health 396 deaths, 79 less than during the preceding week and 137 less than during the corresponding week of the previous year. Of the whole

number 175 occurred in children under the age of five years. The principal causes of death were as follows: Cholera infantum, 60; pulmonary tuberculosis, 36; marasmus, 19; pneumonia, 17; diphtheria, 16; inanition, 13; carcinoma, heart disease, inflammation of the brain, each 12; apoplexy, convulsions, each 12. There were reported during the week 84 cases of diphtheria, 63 of typhoid fever, and 50 of scarlet fever.

The Cause of the Heart Beat.—As the result of an experimental investigation, Porter (*Journal of Experimental Medicine*, July, 1897) arrives at the conclusion that the cause of the rhythmic contraction of the ventricle lies within the ventricle itself. It is not dependent upon a single localized co-ordination centre; the co-ordinative mechanism, whatever it may be, is present in all parts of the ventricle. The apex of the mammalian heart possesses spontaneous rhythmic contractility. Assuming that the general belief in the absence of nerve cells from the apical part of the ventricle is correct, this investigation indicates that nerve cells are not essential to spontaneous, long-continued co-ordinated contractions of the heart muscle.

A Pen Sketch of Pasteur.—In a recent number of *Good Words*, Mrs. Percy Frankland quotes the following description of the great French chemist and man of science, as he appeared a short time before his death: "Weary, traversed with deep lines, his face and beard both white, his hair still thick and nearly always covered with a black cap, the grand forehead wrinkled, seamed with the scars of genius, the mouth slightly drawn by paralysis, but full of kindness, as expressive in pity for the sufferings of others, as indifferent to personal pain, and above all the living thought which still flashes from the eyes beneath the deep shadow of the brow—this is Pasteur."

The Birthplace of the American Medical Association.—The Philadelphia meeting was called the semicentennial, but really to New York belongs the honor of being the birthplace of the American Medical Association. The meeting of physicians held in this city in May, 1846, was properly the first meeting of the association, although it was then without name or other evidences of a formal organization. But it was born then and here—and not one year later in Philadelphia. A baby has no name and not much of a constitution the day he is born, but he's a baby for all that, and when he has grown to manhood, he counts back his years to the day he came into the world, and not to the time he received a name or first encased his nether limbs in knickerbockers.—*Pediatrics.*

What Next?—The latest association formed, according to *Nature*, is for the "Harmonious Development of Faculties," an object which certainly is deserving of sympathy. We may expect soon to hear of the amalgamated societies for the promotion of idiocy. The "association" business is being very much overdone these days, apparently.—*Medical Age.*

The Value of Sterilized Milk.—Dr. Barton draws the following conclusions from a careful study of this subject: 1. Completely sterilized milk, if administered without any fresh food, will undoubtedly sooner or later produce scurvy. 2. Milk that is raised to the boiling-point, or, better, to within two degrees of the boiling-point, and maintained there from five to ten minutes, is "comparatively" sterilized, and will never produce scurvy, and is almost free from pathogenic organisms. 3. Completely sterilized milk, if administered at once in perfectly clean bottles, spoons, or cups, can be relied upon as being free from any pathogenic micro-organisms. 4. The heating of milk alters very little, if at all, its nourishing qualities. 5. All kinds of sterilized milk, if free from added chemicals, can become foul as quickly, if not more quickly, than ordinary fresh milk. 6. All sterilized milk that is put into hermetically sealed vessels, and which can keep fresh in them for many days, will produce scurvy unless some fresh food is administerd daily. 7. Milk that is boiled directly over a fire will undoubtedly cause constipation. If the milk be placed in a vessel which stands in another vessel containing water, and the water be brought to the boiling-point, its antiscorbutic properties are not lost and it does not cause constipation.—*British Medical Journal.*

Health Reports.—The following statistics concerning small-pox, yellow fever, cholera, and plague have been received in the office of the supervising surgeon-general of the United States Marine Hospital service during the week ended August 14, 1897:

CLASSIFICATION AND SURGICAL TREATMENT OF ACUTE PERITONITIS.[1]

N. SENN, M.D., PH.D., LL.D.,

OF CHICAGO.

AN intelligent and systematic discussion of the treatment of acute peritonitis must necessarily be based on a rational classification. A great deal that has been said and written on this subject is worthless, owing to a lack of a proper classification. The classification should include the anatomy, pathology, and etiology of the disease. It is especially important in the discussion of the surgical treatment of peritonitis, before an audience composed of physicians and surgeons, to make a clear distinction between the different clinical forms with a view of pointing out the limitation of purely medical treatment and the legitimate scope of surgical intervention. The clinical classification which I here suggest appears to cover the ground fairly well, but would be incomplete without an exemplification from other standpoints, and for this reason I have prepared the following:

Syllabus of Classification of Acute Peritonitis—*Anatomical.*—Ectoperitonitis, endoperitonitis, parietal peritonitis, and visceral peritonitis, viz., mesenteritis, epiploitis, perigastritis, peri-enteritis, peri typhlitis, peri-appendicitis, pericolitis, perihepatitis, perisplenitis, pericystitis (urinary and gall bladder), perimetritis, perisalpingitis, peri-oöphoritis, pelvic peritonitis, diaphragmatic peritonitis.

Etiological.—Traumatic peritonitis, idiopathic peritonitis, perforative peritonitis, metastatic peritonitis, puerperal peritonitis, peritonitis infantum, fœtal and intra-uterine peritonitis, peritonitis neonatorum.

Pathological.—Diffuse septic peritonitis, putrid, hemorrhagic, suppurative, serous, and fibrino-plastic peritonitis.

Bacteriological.—Streptococcus infection, staphylococcus, pneumococcus, bacillus coli commune, gonococcus, and tuberculous infection.

Clinical.—Ectoperitonitis, general septic peritonitis, perforative, circumscribed, hæmatogenous, visceral (see under anatomical), pelvic, puerperal, and subdiaphragmatic peritonitis.

1. Ectoperitonitis.—An inflammation of the attached side of the peritoneum is called ectoperitonitis. As compared with inflammation of the serous surface, this form is characterized clinically and pathologically by intrinsic tendencies to limitation of the inflammatory process. The mechanical and anatomical conditions for diffusion of the infection are less favorable than when the free surface of the membrane is affected. It may become quite diffuse, however, when the cavum Retzii or the retroperitoneal space on either side of the spinal column is the seat of a suppurative inflammation. In infected wounds of any part of the abdominal wall in which the peritoneum is exposed, but not perforated, the primary ectoperitonitis is occasionally followed by the extension of the infection to the serous surfaces through the lymphatics, or the direct extension of the infective process through the tissues until it reaches the endothelial lining. Peritonitis of visceral origin is always preceded by ectoperitonitis.

The surgical treatment of an ectoperitonitic suppurating focus is curative and prophylactic. The prophylaxis consists in the prevention of rupture of the contents of the abscess into the free peritoneal cavity, by means of an extraperitoneal incision and drainage.

Suppurative inflammation of the loose connective tissue in the cavum Retzii often leads to extensive ectoperitonitis, occasionally to perforation into the peritoneal cavity, septic peritonitis, and death. Leusser found that the loose connective tissue between the peritoneum and the abdominal muscles is divided into two layers by a plane of fascia which is inserted into the upper border of the symphysis. An abscess in this region may therefore be submuscular or prevesical; the former occupies the space between the fascia and the muscles, and assumes an ovate outline with the pointed extremity of the swelling directed downward; an abscess behind the fascia, a true prevesical abscess, resembles in outline the distended bladder. The indications for prompt surgical interference are particularly urgent when the abscess is subperitoneal, as it is in such cases that the peritoneum is extensively involved, and the danger is greatest of extensive burrowing of the pus and perforation into the peritoneal cavity most frequently takes place. The proper treatment of an abscess in the cavum Retzii is an early and free incision made in the same manner and with the same care as in operations for stone in the bladder by the suprapubic route.

2. General Septic Peritonitis.—I understand by a general septic peritonitis an inflammation of the entire peritoneal sac, the result of most virulent infection, the patients dying not so much from the effects of the inflammation as from the rapid introduction into the general circulation of septic material from the peritoneal cavity. In suppurative peritonitis the primary microbic cause is less in quantity or virulence, and a sufficient length of time intervenes between the beginning of the attack and the operation or death for the formation of pus and other inflammatory products. Every acute peritonitis is septic in so far that phlogistic substances reach the general circulation from the inflammatory lesion, but the term septic should be limited to those cases of diffuse septic peritonitis in which, as a rule, death occurs in a few days and before any gross pathological conditions have had time to develop. It is a disease that is almost uniformly fatal with or without operation. The claim of operators to have cured such cases by laparotomy must be accepted with a good deal of allowance. Acute general septic peritonitis is essentially a streptococcus disease. The disease is observed most frequently after perforation into the free peritoneal cavity of an abscess containing septic pus, rupture or perforation of any of the abdominal or pelvic viscera containing septic material, gunshot or stab wounds of the abdomen with injury of the gastro-intestinal canal, and occasionally as the result of infection during lapa-

[1] Abstract of an address delivered before the Twelfth International Medical Congress, held in Moscow, August 19–26, 1897.

rotomy. The gravest form of puerperal sepsis is a diffuse septic peritonitis.

The subjects of this variety of peritonitis die so soon after the beginning of the disease that at the post-mortem or, if the abdomen is opened during life, at the operation no gross tissue changes are discovered. Beside a lightly increased vascularity, nothing is found to indicate the existence of peritonitis. The septic material formed in large quantities and of intense virulence is rapidly absorbed by the stomata of the under surface of the diaphragm, discovered and described by von Recklinghausen. In putrid peritonitis the streptococcus infection is complicated by the presence of putrescible substances which serve as a nutrient medium for saprophytic bacteria which modify the character of the inflammatory product. It occurs most frequently in connection with grave forms of puerperal metritis. Surgery has done much toward its prevention, but very little toward saving life after the disease is once fully developed. Careful analysis of the cases which yielded to laparotomy would undoubtedly disclose the fact that most of them were not genuine cases of general septic peritonitis, but cases of more or less localized inflammation of the peritoneum with or without suppuration.

I have opened, drained, and washed out the peritoneal cavity in many cases of diffuse septic peritonitis, and I am free to confess without a single successful result. All of my patients died in from a few hours to a day or two after the operation, of sepsis, in spite of heroic stimulation and in some cases of frequently repeated irrigation with sterilized water, decinormal salt solution, or mild antiseptic solutions. On the other hand, some surgeons report a fair percentage of recoveries after laparotomy for what they call general septic peritonitis. Krecke has collected one hundred and nineteen cases of laparotomy in general peritonitis, in which there were fifty-one recoveries and sixty-eight deaths. A. J. McCosh operated between 1888 and 1895 inclusive in forty-three cases of general septic peritonitis. Of these thirty-seven died and six recovered, a mortality rate of about eighty-six per cent. A free abdominal incision was made in all, and with few exceptions irrigation was employed.

It is not easy, or always possible, to ascertain the extent of inflammation *in vivo* by opening the peritoneal cavity, and a strong suspicion remains that at least in some of the cases which recovered the peritonitis was not general, or that the operation was performed before the entire serous surface was involved.

A general discussion of the *medical treatment* of peritonitis is out of place here, but a few words in reference to what the surgeon should do and what he should not do in the way of medical treatment when he assumes charge of a case of peritonitis are pertinent to my subject. Stomach treatment must be limited to the administration of liquid food and stimulants. If, as is so frequently the case, nausea and vomiting are prominent symptoms, rectal enemata are of the greatest value. The distressing thirst can often be effectually relieved by high rectal enemata of warm water, and if these are not tolerated by hypodermic infusion. Some authorities favor cathartics, others condemn them and rely on opium. Mr. Tait taught us years ago the value of saline cathartics in the prevention of peritonitis and in its treatment during the incipient stage, and his teachings and practice are not only supported by clinical observation, but have been substantiated by experimental investigations. He has found the most efficient treatment for septic conditions following abdominal section to be thirty or forty grains of sulphate of magnesium, repeated every hour or every other hour until the bowels move freely. I have seen many cases of threatened peritonitis after abdominal section aborted by the timely administration of saline cathartics. If the stomach is intolerant, calomel in small doses, repeated hourly, and saline enemata are indicated. One of the great dangers in peritonitis is rapid distention and paresis of the intestines, conditions which are provoked by opium and which can be most effectually averted by early and free catharsis.

The use of cathartics is, of course, absolutely contraindicated in all cases of peritonitis caused by perforation.

In such cases the use of opium is legitimate and useful, as it diminishes shock, and lessens the extravasation of septic material and its rapid diffusion over the peritoneal surface. Shock, general debility, and, as Fritsch has shown, a weak heart increase the danger from sepsis. Strychnine, camphor, and alcoholic stimulants should be employed early and at short intervals in all cases of grave peritonitis. The application of ice or the cold coil over the abdomen frequently succeeds in diminishing tympanites and should be employed to prevent overdistention and paresis of the intestines when this condition appears, and the state of the peripheral circulation is good. If the heart's action is weak and the capillary circulation sluggish, hot applications are more agreeable to the patient and a better stimulant for the feeble peripheral circulation.

There can be no difference of opinion in reference to the advisability of early *operative treatment* in the management of general diffuse septic peritonitis. Without operation death is certain. An early operation may succeed in arresting further extension of infection in cases in which the disease would become diffuse, and in diffuse cases may occasionally be the means of saving a life which without it would be surely lost. An early diagnosis and prompt operative interference are the conditions *sine qua non* of success. The patient should be properly prepared for the operation, not only with a view of securing absolute asepsis for the field of operation and everything that is to be brought in contact with the wound, but the necessary precautions should also be carried into effect to sustain the heart's action and stimulate the capillary circulation during and immediately after the operation. I am partial to the use of sulphuric ether as an anæsthetic in performing laparotomy for this indication, as it has a less injurious effect upon the already enfeebled circulation than chloroform. The body must be carefully protected against loss of heat, by warm flannel blankets and by bottles or rubber bags containing hot water. The solutions which are to be used for irrigation must be kept at a temperature of 110° to 120° F.

Laparotomy, as a therapeutic resource in the treatment of peritonitis, is of recent date. J. Ewing Mears as early as 1875 operated by abdominal section in a case of circumscribed suppurative peritonitis following childbirth. He advocated at that time surgical intervention in all cases of suppurative peritonitis. Treves reported a case of acute peritonitis treated by abdominal section in 1885, which terminated in recovery, and he recommended the operation in similar cases. During the same year Péan advocated in the treatment of septic peritonitis incision, toilette, and drainage of the abdominal cavity. About the same time Oberst urged energetic surgical treatment in cases of acute peritonitis. In 1886 Lawson Tait reported two cases of acute peritonitis treated by abdominal section, of which one recovered. He advised laparotomy in all cases of peritonitis if an effusion can be demonstrated and the existence of fever indicates the pyogenic nature of the inflammatory product. In 1889 successful laparotomies for septic peritonitis were reported by Demons, Bouilly, Dernuce, Brun, Labbe, and Routier. It is evident that in most of these cases the operation was performed for circumscribed suppurative, and not for diffuse septic peritonitis.

The treatment of peritonitis by laparotomy received

a new impulse when about nine years ago it was found that the disease is so often produced by primary suppurative and perforative lesions of the appendix vermiformis.

Incision.—Authorities are as yet not agreed as to the size, location, and number of incisions. In circumscribed peritonitis the rule is usually followed to open and drain by the shortest and most direct route. In perforation of any organ other than the appendix vermiformis, resulting in diffuse peritonitis, the first incision should always be made at or near the median line. The incision is made above the umbilicus if the gall bladder, stomach, or duodenum is the seat of perforation, below the umbilicus in perforation of any other portion of the small intestines.

Mikulicz makes a sharp distinction in the treatment of diffuse septic and progressive fibro-purulent peritonitis. In the former the abdominal incision should be large, the perforation closed, and the abdominal cavity disinfected and drained. In the latter the adhesions should be carefully preserved and the different pus accumulations opened and evacuated separately. Some surgeons prefer to open the abdomen some distance from the linea alba. Ramsay gives cogent reasons why the incision should be made through the centre of either rectus muscle, where the abdominal wall is thickest and strongest and where the different layers can be sutured separately with the greatest ease, and where for these reasons ventral hernia is least likely to follow. Prolonged drainage is always an important etiological element in the occurrence of postoperative ventral hernia, and this complication is certainly less likely to follow if the incision is made through the muscular portion of the abdominal wall than through the thin fibrous linea alba.

In the treatment of diffuse septic peritonitis the incision should be at least large enough to insert the hand for the purpose of making a careful intra-abdominal exploration. Mr. Bowlby is of the belief that an incision below the umbilicus does not necessarily empty the peritoneal cavity. In cases of peritonitis resulting from perforation of a gastric or duodenal ulcer he advises two incisions (one above and one below the umbilicus) to insure complete flushing. In diffuse peritonitis incisions should be made at a number of points with a view to facilitate irrigation and insure free drainage. The best points will be above the pubes, above the umbilicus, and posteriorly through the lumbar region on each side. In woman free drainage into the vagina by incising Douglas' cul-de-sac will answer an excellent purpose.

McBurney has devised an incision for operations upon the appendix that reduces to a minimum the risks of a subsequent formation of a ventral hernia. "The skin incision is oblique, about four inches in length, crossing at a right angle a line drawn from the spine of the ilium to the umbilicus and about an inch from the spine. This incision is a little to the outer side of the normal situation of the appendix. The fibres of the external oblique and its aponeurosis are not cut, but are separated with great care in the direction in which they run. When the edges of the wound of the external oblique are separated with retractors, a considerable expanse of internal oblique muscle is seen, the fibres of which cross somewhat obliquely the opening formed by the retractors. With a blunt instrument the fibres of the internal oblique and transversalis muscle can be separated, without cutting more than an occasional fibre, in a line parallel with their course, that is, nearly at right angles to the incision in the external aponeurosis. Blunt retractors are now introduced, and these expose the transversalis fascia, which is then divided in the same line; last of all the peritoneum is divided." This incision is an ideal one for the removal of a diseased appendix not complicated by suppurative peri-appendicitis. In the latter event the incision must be large enough to enable the surgeon to see what he is doing in order to avoid injuring important neighboring organs.

Eventration.—A number of surgeons favor eventration, after incising the peritoneal cavity freely, in order to obtain more thorough disinfection. In septic peritonitis the serous coat of the intestines is always damaged and frequently the muscular coat is paretic. These conditions render them liable to be injured and even ruptured when extensive eventration is made, to say nothing of the shock which always attends such a procedure.

I have seen the dangers of extensive eventration many a time in the operative treatment of intestinal obstruction, and wherever possible I am only too anxious to reach without it the object for which operation is performed.

Irrigation.—Some surgeons invariably irrigate; others believe that irrigation does more harm than good and are content to remove the inflammatory products by means of sponges. It is generally conceded that in diffuse peritonitis it is impossible, by any known methods of irrigation, to remove all of the infectious material from the peritoneal cavity, yet the surgeon resorts to irrigation almost instinctively to diminish the danger from this source. The use of strong antiseptic solutions has been abandoned, and sterilized water, decinormal salt solution, solutions of boric acid or acetate of aluminium, and Thiersch's solution are now most frequently used. Whatever solution is employed it should be used at a temperature of 110° to 115° F., and the stream should be sufficiently large and strong to wash out the most remote corners of the peritoneal cavity in the direction of the drainage opening or openings.

Reichel's attempts to treat septic peritonitis, artificially produced in animals, were almost entirely a failure. Irrigation of the peritoneal cavity with sublimate, chloroborate of sodium, salicylic acid, etc., were useless; the animals quickly perished. Somewhat better results were obtained by sponging gently the peritoneal surfaces with gauze sponges and employing the Mikulicz gauze drain. In nine experimental cases in dogs, two recoveries were obtained by this method. Reichel believes successful operative treatment is applicable only in cases of circumscribed empyema-like pus accumulations. Delvet speaks more favorably of the results of irrigation of the peritoneal cavity. He advocates the use of salt solution in operations upon the abdominal cavity, when contamination takes place during the operation, and in the operative treatment of septic peritonitis. Barker has found by experience that a very convenient method of flushing the abdominal cavity is to use a can with three taps to which tubes of large calibre are attached, and thus the peritoneal cavity can be flushed from several points at once, the fluid flowing out through the original incisions. Wiggin believes that the use of peroxide of hydrogen, followed by plenty of decinormal salt solution, is most beneficial in disinfecting the peritoneal cavity and in preventing adhesions.

Continuous irrigation, which is useful in the treatment of septic wounds in other localities, has been suggested in the treatment of general peritonitis.

The propriety of tearing up adhesions for the purpose of making the irrigation more thorough is very questionable and as a rule should be avoided. The so-called toilette by using sponges must be done with the utmost gentleness, if resorted to at all, as all mechanical insults inflicted upon the endothelial surface are sure to aggravate the existing conditions. If it is intended to remove the fluid from the peritoneal cavity, it is better to do so by placing the patient on

the side so as to pour it out instead of removing it by mopping.

Incision of Overdistended Intestine.—One of the most unfavorable conditions in peritonitis is overdistention of the intestines with gas and septic fluid material. A paretic inflamed intestine is permeable to pathogenic microbes, thus adding another fruitful source of infection to the existing septic inflammation. It is natural that surgeons should have made attempts to relieve the distention and unload the intestines of septic material by tapping or by making one or more incisions. Mixter recommends incision of the coils of the paretic intestines at as many points as may be necessary to evacuate them. The intestines should be drawn out of the wound, held over a basin, incised in from one to four places, and thoroughly emptied, after which the coils should be quickly washed off with a hot saline solution, the visceral wounds sutured, the intestine returned, and the abdominal incision closed. I have made visceral incisions in a number of cases in which the intestine had become paretic, and, although but one of the patients recovered, I am firmly convinced that it is almost essential to success in such desperate cases. I place the patient on the side, bring the most distended part of the intestine well forward into the wound, and make a transverse incision about an inch in length opposite the mesenteric attachment. As the intestinal wall does not contract, evacuation should be secured by pouring out the contents from above and below the incision by grasping the intestine at some distance away and bringing it above the level of the incision. By this method several feet of intestine can be evacuated through one incision. After thorough cleansing of the exposed intestinal surface with warm salt solution the wound is sutured in the usual manner and the intestine is returned.

Drainage.—Drainage of the abdominal cavity after operations for peritonitis is an admission of the present imperfect state of surgery; it is an acknowledgment on the part of the surgeon that he has only in part fulfilled the indications for which the operation was performed; it is a confession that he was not able to accomplish what was so much needed and what he so earnestly desired—complete asepsis of the entire peritoneal cavity.

In 1870, during the Franco-Prussian war, Marion Sims made a special study of the cause of death in cases of gunshot wounds of the abdomen. He found that with few exceptions, if the bullet entered above the pelvis the case proved fatal, while similar wounds of the pelvic portion of the abdominal cavity ended in recovery. He ascribed this difference in the mortality to the circumstance that high wounds resulted in extravasation of the intestinal contents which accumulated in the pelvic cavity, while in pelvic wounds the track made by the bullet served as a drainage canal. In 1872 he recommended that in all penetrating wounds of the abdomen and in operations on any of its contents drainage should be established. Very few surgeons at the present day would feel justified in opening the abdominal cavity for peritonitis and dispensing with drainage. Voices have, however, been raised against too frequent resort to drainage, among them Olshausen, who says: "Drainage of the peritoneal cavity is an illusion. Drainage to be of service must be limited to the evacuation of preformed pathological spaces." In perforating wounds he recommends a careful cleansing and complete hæmostasis, avoiding drainage in all recent cases.

Barker relies mainly on thorough flushing and sutures the abdominal incision. He resorts to drainage only in the treatment of putrid abscesses caused by appendicitis. If a drain is used in exceptional cases of peritonitis he advises its removal at the expiration of twenty-four hours.

At present there are three methods of drainage in general use: 1. Tubular drainage; 2. Capillary drainage; 3. A combination of tubular and capillary drainage.

Tubular drainage is especially indicated in cases in which the abdominal cavity contains pus. The tubes employed are made of either glass or soft rubber. Keith's glass drains answer an excellent purpose in draining the lowest portion of the abdominal cavity. They should be slightly curved at the abdominal end so as to reach the floor of the pelvic cavity without making harmful pressure against the bladder. Frequent aspiration of the contents of the drain is necessary for the purpose of removing the fluid inflammatory product as soon as it is formed. The rubber drain answers the same purpose, but is justly accused of causing more mechanical irritation than the smooth glass tube. Prolonged tubular drainage has not infrequently caused intestinal fistula by pressure. It is for this reason that I now almost invariably surround the rubber or glass tube with a few layers of iodoform gauze securely fastened to the tube. In draining the pelvic porton of the abdominal cavity I frequently use two drains of the size of a little finger, one on each side, brought out through the same opening in the lower angle of the wound. In draining in the lumbar regions and through the vagina rubber drains should be employed.

Capillary drains are frequently employed as substitutes for the tubular drain and in addition must often be relied upon as an important hæmostatic resource in arresting parenchymatous oozing. The name of Mikulicz is connected with a special method of gauze drainage of his own device, which has proved of great value in the surgical treatment of peritonitis. The typical Mikulicz tampon is made by taking a piece of iodoform gauze the size of a large handkerchief, to the centre of which a strong piece of aseptic silk thread is stitched. When used it is arranged as a pouch and is carried by means of curved forceps to the bottom of the pelvis and is filled with strips of iodoform gauze, the free end of the silk thread issuing from the mouth of the pouch. When it is desired to remove the drain the gauze strips are drawn out and the pouch is removed by making traction upon the string. In dealing with large cavities requiring an enormous amount of gauze I have learned to fear iodoform gauze, because the cases are by no means isolated in which a drain composed exclusively of iodoform gauze became the immediate cause of death from iodoform intoxication. This is particularly liable to occur in cases in which the patient's kidneys are not functionating properly. I should, therefore, limit the iodoform gauze to an outer layer or two and pack the pouch with ordinary sterilized gauze.

Drainage by sterilized wicking has been popular in Germany for a number of years and in many cases has answered an excellent purpose. It has never found its way to any extent into America, where gauze is employed in preference. R. T. Morris recommends wicks which he employs in a peculiar way. The simplest wick consists of a little roll of bichloride gauze, around which is wrapped a couple of thicknesses of Lister's protective silk. The gauze protrudes a little from each end of the cylinder, and a few small fenestræ in the protective silk allow the serum to reach the gauze elsewhere. When a large gauze packing for the pelvis or abdomen is needed, an apron of the silk can expand over the gauze and protect against intestinal adhesions. This method possesses great advantages over ordinary tubular and capillary drainage, and recommends itself more especially in the surgical treatment of diffuse septic peritonitis. The prolonged contact of gauze with a serous surface is very prone to give rise to permanent adhesions, as

every clinician knows. In employing gauze in draining the peritoneal cavity it is necessary to use long strips which should be inserted in different directions and brought out at the same place and fastened together with a safety pin. Van Hook has shown that the gauze drains more freely if the external ends are left long and placed on the side of the pelvis below the level of the wound. Drainage must be dispensed with as soon as possible, in order to prevent adhesions and to enable the surgeon to close the incision by secondary suturing, an important precaution against the formation of a ventral hernia. The strips should be shortened, and one after the other removed as the indications for drainage disappear.

The simultaneous use of tubular and capillary drainage is an excellent method. It is effected by packing loosely a glass drain of proper length and size with strips of gauze or aseptic wicking. This is especially useful when the inflammatory product is serum instead of pus.

Intra-Intestinal Saline Injections. — The value of saline cathartics in the treatment of incipient peritonitis not caused by perforation is now generally recognized. One of the difficulties encountered in the treatment of such cases is the intolerance of the stomach to food and medicines. A. J. McCosh has succeeded in securing free catharsis and in overcoming the intestinal paresis after operations for peritonitis by injecting into the small intestine, at a point in the jejunum or in the ileum, as high up as possible, a saturated solution containing between one and two ounces of sulphate of magnesium.

After-Treatment.—In all cases the most attentive and careful after-treatment is essential to success. The patients are prostrated by the disease and the operation, and require a stimulating treatment. External dry heat is an important element in counteracting the shock and in restoring the peripheral circulation. The thirst is quenched most effectually by subcutaneous infusion or rectal enemata of water. Strychnine and alcoholic stimulants are best calculated to increase the force of the heart's action and the tone of the arterial circulation. Partial inversion of the body by raising the foot of the bed and also autotransfusion are potent means of inducing cardiac stimulation. A well-fitting abdominal bandage applied firmly exerts a favorable influence in preventing and diminishing abdominal distention. Saline cathartics should be administered as soon as the stomach is in a condition to absorb them. Meteorism can often be relieved by high turpentine enemata and the use of the elastic rectal tube.

As no operation ever secures completely aseptic condition of the peritoneal cavity in cases of general peritonitis, Marmorek's streptococcus antitoxin may prove a useful adjunct to the after-treatment. A number of cases have recently been reported in which the serum appears to have been of great value in the treatment of septic conditions in the peritoneal cavity and elsewhere. It is not probable that it will ever displace the knife in the treatment of diffuse general septic peritonitis, but it is more than probable that it will prove to be an important therapeutic agent in the treatment of peritonitis before and after operation. Opium should be used with great caution. The external dressing should be changed as soon as it has become saturated. If continuous irrigation is decided upon a decinormal salt solution at a temperature of 105° F. is the one usually employed. The current should be small and without much force. The outflow from the peritoneal cavity should be received upon a rubber blanket and conducted into a receptacle near the bed. This method of irrigation recommends itself particularly in cases of diffuse septic peritonitis. In suppurative diffuse peritonitis periodical flushings, at intervals of two or three hours, will prove of value in removing from the peritoneal cavity the fluid products of the inflammatory process. The solutions best adapted for this puprose are a saturated solution of the acetate of aluminium, a three to five per cent. solution of boric acid, or Thiersch's solution. Drainage when once established should be suspended gradually and not suddenly. As soon as the peritoneal cavity and the drain canals are aseptic the external wound should be sutured, to prevent as far as possible the subsequent formation of a ventral hernia.

3. Perforative Peritonitis.—Perforative peritonitis invariably occurs as a secondary affection, usually in connection with an ulcerative or gangrenous lesion of some part of the gastro-intestinal canal. Penetrating wounds of the abdomen with injury of the gastro-intestinal canal must be regarded in the same light as perforative lesions of the abdominal organs in the causation of peritonitis. Perforative peritonitis is manifested by the sudden onset of diffuse pain and tenderness, rigid abdominal walls, fever, vomiting, and the presence of gas in the free peritoneal cavity. According to my observation, peritoneal meteorism in perforative peritonitis caused by appendicitis is rare, while I have seldom found it absent after perforation of any other portion of the gastro-intestinal canal. According to the number and virulence of the microbes which find their way into the peritoneal cavity with the extravasation, the resulting peritonitis is either diffuse or more or less circumscribed. The colon bacillus is invariably present in the inflammatory product, but others, according to the nature of the primary affection, may also be found. Perforative peritonitis must be treated as a strictly surgical disease. The perforation should be found and properly treated before a general septic peritonitis has had time to develop. There are exceptions to this rule in cases in which the perforation is small and the extravasation has produced a limited peritonitis in a locality where it is safe to wait for abscess formation, as is often the case in the region of the gall bladder and appendix vermiformis. Penetrating wounds of the abdomen with visceral lesions of sufficient extent to give rise to extravasation call for immediate laparotomy.

Perforating Gastric Ulcer.—Perforating ulcer of the stomach is found most frequently on the anterior wall near the small curvature. Perforation in this locality is followed more constantly by diffuse peritonitis than is that through the posterior wall. The onset of the disease is always sudden, no matter what the antecedent symptoms may have been. Shock is present in greater or less degree. Vomiting, though frequent, is not constant. Abdominal pain and tenderness, increased by pressure, are nearly always present; abdominal rigidity in the early stage, and distention later on, are frequently noted. The duration of the cases varies from a few hours to five days, most of them terminating in death in less than twenty-four hours.

Mikulicz performed the first operation for this condition in 1883. The first successful case was reported by Kriege, of Berlin. The incision should be made in the median line from the ensiform cartilage to the umbilicus, and enlarged if necessary. If the posterior wall is perforated and the perforation cannot be reached in the usual manner, the anterior wall is incised and the perforation closed through this incision. Before the perforation is sutured the stomach should be emptied through a stomach tube, or through the opening. It is not necessary to excise the margins of the ulcer, as these can be inverted in tying the Lembert sutures. Should the wall of the stomach in the immediate vicinity present an unfavorable condition for successful suturing, an omental flap or graft or requisite size should be sewed with catgut over the line of suture.

Perforating Ulcer of the Duodenum.—This occurs suddenly and frequently without any marked premonitory symptoms indicative of the existence of the primary disease. It is only recently that peritonitis resulting from this cause has been subjected to operative treatment. The ulcer is usually in the first part, but may be in either of the other two portions. The ulcer is simply inverted, excision being unnecessary. Drainage must also be provided for.

Perforating Typhoid Ulcer.—Perforation of a typhoid ulcer, large enough for extravasation to take place into the free peritoneal cvaity, is a fatal accident, death ensuing in the course of a day or two. Perforation, however, does not always terminate in that way. Extravasation is often prevented by the affected part of the intestinal wall becoming attached to an adjacent serous surface, thus protecting the peritoneal cavity against infection. I have seen several cases of typhoid fever in which, about the time that perforation is most likely to occur, circumscribed peritonitis set in which could have been caused only by a perforating ulcer under such favorable conditions, and from which the patients recovered without operative intervention.

Kussmaul, in October, 1885, was the first to excise and suture a perforating typhoid ulcer. Lueck performed laparotomy for the same indication on October 22, 1885.

Wiggin collected twenty-four cases of perforating typhoid ulcer subjected to laparotomy with six recoveries. If those cases are rejected in which the diagnosis is somewhat doubtful, there are seventeen patients with three recoveries. The first successful result was obtained by Van Hook, the second by Netschajans, the third by Abbe. J. Price has recently reported three consecutive operations with as many recoveries, a surgical feat which it will be difficult to duplicate. The writer has performed the operation three times with one recovery. The feasibility and justifiability of abdominal section for perforating typhoid ulcer have been established in view of the fact that all of the patients who have been operated upon would have died without the operation. The operation should be performed as soon as possible after the accident has occurred. The mortality will always remain great, owing to the debilitated condition of the patients and the existence of multiple ulcers.

4. Circumscribed Peritonitis.—This is an inflammation of the peritoneum during which a greater or lesser part of the peritoneal cavity becomes excluded from the original source of infection by the formation of plastic visceral, parietal, or visceral and parietal adhesions. The symptoms appear suddenly, or are preceded by those incident to the primary disease. The intensity of the general symptoms is determined more by the nature and virulence of the microbic cause than the area of the peritoneal surface involved. The clinical course and termination are determined largely by the nature of the bacterial cause, the abdominal location of the primary starting-point, and nature of the environment. Localized peritonitis is most likely to occur outside of the limits of the small-intestine area. It may be confined to the lesser omental cavity, particularly in cases of perforating ulcers of the stomach and duodenum. More frequently it is caused by appendicitis and cæcitis. A very frequent cause of circumscribed peritonitis is inflammation about the gall bladder, uterus, Fallopian tubes, or ovaries. Localized peritonitis can usually be detected only if a demonstrable swelling forms at the seat of inflammation. The mildest form of infection gives rise to fibrino-plastic peritonitis, which leaves temporary or permanent adhesions but terminates without suppuration. Circumscribed suppurative inflammation is always attended by fibrino-plastic peritonitis, the products of which and the viscera which it involves form the abscess wall. In fibrino-plastic peritonitis surgical interference becomes necessary only when intestinal obstruction is caused by adhesions. In circumscribed suppurative peritonitis the pus should be evacuated as soon as the disease is recognized and if possible by an extraperitoneal route.

Acute Tuberculous Peritonitis.—Tuberculous peritonitis, usually circumscribed, occasionally presents itself as a widely diffused acute affection. According to the intensity of the infection or the degree of susceptibility of the patient to the action of the tubercle bacillus, the disease assumes one of the following forms: (1) Tuberculous ascites; (2) fibrino-plastic peritonitis; (3) adhesive peritonitis. Suppuration takes place only when the tuberculous product becomes the seat of a secondary mixed infection with pus microbes. Laparotomy is now a well-established operation in tuberculous peritonitis, but the exact manner in which the operation exerts its therapeutic influence is not well understood. I have obtained very satisfacory results, in cases which resisted laparotomy and drainage, by repeated tappings and injections of two to four drachms of a ten-per-cent. iodoform-glycerin emulsion.

Suppurative Peritonitis.—Suppurative peritonitis is always more or less circumscribed. It is generally associated with fibrino-plastic exudation. The accumulation of pus may be so large that upon opening the abdomen it may appear as though the entire peritoneal cavity and all of the organs contained within were implicated, but a careful examination will almost always reveal the fact that a large part of the peritoneal cavity and many of the organs are shut out from the inflammatory process by plastic adhesions. The appearance and character of the pus are often greatly modified by the admixture of an extravasated material. If the pus is thin and serous, we speak of a sero-purulent peritonitis. It is a serous peritonitis with the formation of pus in sufficient quantity to render the serum more or less turbid. This subvariety of suppurative peritonitis is without exception accompanied by fibrinous exudations which tend to limit the extension of the infective process. Sedimentation of the solid constituents takes place, so that the fluid contains more of the solid matter in the most dependent portion of the affected district.

Fibrino-Plastic Peritonitis.—This is a very frequent form of circumscribed peritonitis. It is usually secondary to an affection of one of the abdominal or pelvic organs. The exudation is often so copious that it has been mistaken for malignant disease. The exudation in the course of time contracts and results in strong bands of adhesion which frequently flex and distort the organs to which they are attached; this has given rise to the term, *peritonitis deformans.*

The surgical treatment of circumscribed peritonitis by abdominal section has yielded very encouraging results. The extraperitoneal route is the one of choice in all cases in which the abscess cavity can be safely reached and efficiently drained. In circumscribed accumulations of pus in the peritoneal cavity in which the seat of the disease must be reached through the free abdominal cavity, the safest course to pursue is to perform the operation in two stages. The first operation then consists in suturing the parietal peritoneum to the wall of the abscess cavity, suturing the abdominal incision with the exception of a space large enough to incise and drain the abscess cavity later. This space is packed with iodoform gauze and two or three days later the abscess is incised and drained. If the symptoms are urgent and the operation must be completed, the contents of the abscess cavity should first be removed by aspiration. In fibrino-plastic peritonitis without suppuration no

attempt should be made to tear the adhesions unless they have caused intestinal obstruction. Some surgeons, however, aim to remove the fibrinous exudate with the pus. Demona had under his care a woman suffering from suppurative peritonitis following suppuration of an ovarian cyst. Her condition at the time of operation was critical. He opened the abdomen, evacuated the pus, removed the cyst, and, with a rough sponge and blade of a knife, scraped the entire surface of the intestine; a most satisfactory recovery followed. There are few surgeons who would follow his example to-day. Adhesions tend to limit the infective process and should be interfered with as little as possible.

5. Hæmatogenous Peritonitis.—Idiopathic peritonitis, so-called, or hæmatogenous peritonitis may occur, but is much more rare than a similar affection of the pleura and pericardium. As peritonitis is always caused by bacteria of some kind, a peritonitis that develops independently of a local cause is the result of an infection through the blood and should be called hæmatogenous or metastatic peritonitis. It has been observed in connection with nephritis, pyæmia, rheumatic arthritis, and acute exanthematous diseases. In the absence of even a distant focus of infection it is plausible to assume that peritonitis in very rare cases is caused by the localization of pus microbes from the blood in some part of the peritoneum prepared for their reception and growth by some antecedent injury or disease.

The surgical treatment must be guided by the location and the extent of the disease, the existence or absence of complications, and the pathological type the disease presents at the time of operation.

6. Visceral Peritonitis.—The inflammatory process is seldom limited to a single organ, as during the course of the disease adjacent organs or the parietal peritoneum will surely become involved. In inflammatory and rheumatic affections of the abdominal walls and the abdominal and pelvic viscera, plastic inflammation of the omentum frequently constitutes the safeguard against infection of the general peritoneal cavity by the omentum becoming firmly attached over a threatened perforation or visceral or parietal wound. The surgeon often imitates nature's process and makes use of the omentum in covering denuded surfaces or those where perforation threatens. The surgical treatment of appendicitis and its various complications is not well settled at the present time. Some surgeons advise operation in all cases in which a diagnosis of appendicitis can be made, regardless of the nature of the disease and the character of its complications. The more conservative element of the profession limits the use of the knife to cases in which there are positive indications for surgical interference. For my own part I resort to operation in all cases during a first attack, when the symptoms point to perforation or gangrene of the appendix. The sooner the operation is undertaken under such circumstances the better the results. The appendix should be sought for and removed only if pus is found in the iliac fossa, and when it can be done without a material increase in the immediate risks of the operation; otherwise the treatment by incision and drainage will yield the best results. In mild cases of appendicitis from eighty to ninety per cent. recover under appropriate medical treatment and in a fair percentage of cases the disease does not return. The gravest cases are those in which the affection of the appendix is followed by diffuse peritonitis. In the treatment of this class of cases nearly all surgeons are fully in accord with the rules laid down by McBurney in an article in THE MEDICAL RECORD, March 30, 1895. In relapsing appendicitis an operation is indicated, particularly in cases in which the attacks set in at short intervals and with gradually increasing intensity. In peritonitis resulting from infective lesions of the uterus, ovaries, or Fallopian tubes, the organ primarily affected and the resulting intraperitoneal abscess can often be reached more safely by a vaginal than by an abdominal operation. Occasionally the combined operation will be better.

7. Pelvic Peritonitis.—Pelvic peritonitis is seldom met with in the male. It is a form of peritonitis in which the female pelvic organs are the primary starting-point of infection with extension to the peritoneum, through either the Fallopian tubes or the lymphatics of the uterus or of its adnexa. It is caused most frequently by gonorrhœal or puerperal infection, or develops after instrumental examination of the interior of the uterus or operation upon that organ. In pyogenic infection the inflammation may become diffuse, and if circumscribed usually leads to the formation of parametritic or intraperitoneal abscesses, or pus formation takes place in both of these localities. In the peritoneal cavity the gonococcus produces a plastic peritonitis, and sometimes localized suppuration. Salpingo-peritonitis and more diffuse pelvic peritonitis are most frequently caused by gonococcus infection. Abdominal section is seldom performed for gonorrhœal peritonitis during the acute stage. An early incision through the vaginal roof into the cul-de-sac of Douglas, so strongly urged by Henrotin, is a rational procedure and frequently succeeds in preventing the extension of the infection and the occurrence of serious remote complications. I have in several instances incised and drained the Fallopian tube through such an incision, and in this way prevented further leakage from the tube into the peritoneal cavity, and thus directly cut off additional supply of infectious material. The treatment of large parametritic abscesses by an extraperitoneal incision is preferable to a transperitoneal operation in all cases in which the abscess can be reached by this route.

We shall hear less of intestinal, vesical, and rectal fistula as the remote result of pelvic peritonitis or parametritic abscesses as soon as the profession recognizes fully the necessity of timely operative interference.

8. Puerperal Peritonitis.—By this term is understood a progressive inflammation of the peritoneum, occurring in consequence of an extension of an infection from any part of the genital tract in puerperal women after delivery or abortion. The infection usually takes place through the lymphatics, and in the majority of cases terminates in diffuse septic peritonitis. In some instances the disease remains limited to the pelvic organs and their serous investment; then abscess formation, intra- and extra-peritoneal, is very likely to occur.

The treatment of the localized form of puerperal peritonitis is the same as that advised in circumscribed peritonitis resulting from other causes. The foudroyant form of puerperal sepsis proves fatal in spite of the most energetic medical and surgical treatment. The use of the streptococcus antitoxin may prove of great value and should receive an early and fair trial. It has been suggested that early removal of the infected uterus would prevent the extension of the disease to the peritoneum and death from sepsis, but the results have not been encouraging. It is exceedingly difficult, and in many cases absolutely impossible, to make a sufficiently early and positive diagnosis to warrant such a grave and mutilating operation as a timely and life-saving measure. If the uterus is removed after general septic peritonitis has developed, the operation is performed too late and death from shock and sepsis is the rule.

9. Subdiaphragmatic Peritonitis.—This is a peritonitis limited to the under surface of the diaphragm and adjacent surfaces of the abdominal organs. If

the inflammation remains limited and life is sufficiently prolonged, it usually terminates in the formation of a subdiaphragmatic or subphrenic abscess. Perforating ulcer of the stomach and duodenum, abscess of the spleen and liver are the most frequent affections which precede subdiaphragmatic peritonitis. Subphrenic abscess often ruptures into the pleural cavity, and in cases of empyema the possible existence of a subphrenic abscess must be kept in mind.

Accurate location of the abscess and the positive diagnosis are made by exploratory puncture. As perforating ulcer of the stomach is the most frequent cause, subphrenic abscesses are more frequently located on the left than on the right side. Occasionally a spontaneous cure occurs by perforation of the abscess into a hollow adjacent organ. The satisfactory results of operation in these cases furnish the most conclusive proof regarding its necessity and life-saving value.

ON THE RELATION OF PHYSIOLOGY, PHARMACOLOGY, PATHOLOGY, AND PRACTICAL MEDICINE.[1]

By T. LAUDER BRUNTON, M.D., D.Sc. Edin., LL.D. Hon. Aberd., F.R.C.P., F.R.S.

The desire for knowledge which is common to the lower animals and man, savage or civilized, and has induced members of this congress to come from the ends of the earth in order to gain information, must have led primitive man from the earliest times to study the great problems of physiology, the nature of life, of growth, of reproduction, and of death, as well as to notice the connection of the latter with mechanical injuries, such as the wounds inflicted by clubs and spears or by the teeth and claws of wild beasts.

Next to the problems of physiology come those of pharmacology, by which I mean the poisonous or remedial action of various substances mineral, vegetable, or animal. A knowledge of this subject is found even among the lowest savages, and is of the greatest use to them, for it enables them, on the one hand, to avoid eating things which may cause discomfort, pain, or death, and, on the other, to obtain food by poisoning waters and thus catching fish, or by poisoning their arrows to kill game which would otherwise escape. Closely associated with the knowledge of the poisonous is that of the curative powers of herbs, and it is possessed by animals as well as man, for cows avoid noxious plants, and dogs will every now and again eat grass apparently as medicine. Primitive peoples use various substances as remedies in disease, with more or less success, and one of the most extraordinary points in their practice is that they seem to some extent to have forestalled the newest researches on venins, antivenins, and organotherapy, for in Africa the Bushmen are accustomed to drink the poison of venomous snakes as a prophylactic against their bite, and the Hausas prevent hydrophobia by killing the mad dog and making the man it has bitten eat its liver.

The occurrence of death from wounds or poison is intelligible even to a savage, but when illness and death occur independently of these, men naturally attribute them to invisible powers. Thus the Dyaks of Borneo ascribe sickness to wounds from invisible spears wielded by invisible spirits, and during an epidemic of disease in the Middle Ages the cry often arose that the wells had been poisoned. These crude ideas contain germs of truth, and when we look at Professor Metschnikoff's drawings of a Daphnia attacked by a Monospora we seem to recognize the invisible darts of the Dyaks, while during an epidemic of typhoid fever we have often to acknowledge that our wells have been poisoned by bacilli.

It is impossible to trace the steps by which the crude ideas of savage peoples regarding physiology, pharmacology, and pathology have grown into definite sciences, or even to indicate the most important landmarks, though we naturally think of the names of Alkmaon, Galen, and Harvey in physiology; of Nicander, Magendie, and Bernard in pharmacology; and of Morgagni, Virchow, and Pasteur in pathology. During this century these three sciences have developed with almost incredible rapidity; a complete knowledge of them is enough to tax severely the most retentive memory, and it is almost impossible for any individual to keep up with the advance of all three of them.

But just as the whole subject of astronomy became suddenly simplified by a change of standpoint at the very time when cycles and epicycles became most bewildering, so at the very time when these three sciences are becoming most complex and diverse they appear to be tending to unification and simplification. Pathology, for example, is now becoming to a great extent a branch of pharmacology, for while a few years ago its chief object was to discover, examine, and classify the microbes which give rise to disease, it is now striving rather to discover the nature and actions of the ferments and poisons which they form, and by which they are able to cause disease and death in the animals they attack. Pharmacological investigation, instead of being confined to the alkaloids and other poisons formed by higher plants, has now extended to those formed by microscopic plants or microbes, and thus comes to include a great part of pathology.

In the same way, though pharmacology is a branch of physiology, inasmuch as it deals with the phenomena of life as modified by drugs, yet physiology may, to a certain extent, be regarded as a branch of pharmacology, because some of the latest researches regarding the processes of life have been made by pharmacological methods, using the products of animal life instead of vegetable poisons. Among the pioneers in this line I may mention my two masters, Kühne and Ludwig; the former of whom by his chemical investigations has enabled us to differentiate the various products of albuminous decomposition, while the latter, with his pupils, Schmidt-Mühlheim and Wooldridge, discovered the poisonous action of albumoses and peptones, and of the juices of various tissues when injected directly into the blood.

Before the proteid constituents of our food can be absorbed they must be split up during digestion into albumoses and peptones; yet these researches show that the very substances which are necessary to repair waste and are indispensable for the continuance of life prove fatal when introduced into the body in a wrong way or in too great quantity. But the products of the digestion of albumin do not normally enter the circulation as albumoses and peptones. During absorption they undergo changes of a synthetic nature in the walls of the intestine, and probably to a certain extent also in the liver, so that they again form harmless substances, and their poisonous properties are destroyed before they enter the general blood stream.

But how is it that the ferments which decompose albuminous food and form poisons from it in the intestine do not pass into the blood and kill the animal by digesting the tissues and forming poisons from them? Of course pepsin cannot do so, as it acts only in an acid medium, but there is no such hindrance to the action of trypsin, and yet it does not destroy the tissues composing the body itself. In all probability

[1] An address delivered before the Twelfth International Medical Congress, held in Moscow, August 19-26, 1897.

the reason why digestive ferments do not digest the tissues is not that they are destroyed in the digestive canal, nor yet that they are not absorbed, but that they are altered from active enzymes into inert zymogens which can be stored up without risk, and can again liberate active enzymes when these are required to digest a subsequent meal. In this respect they may be compared to the knives used by wandering peoples to cut up their meat, and which are not thrown away after each meal, but are simply put into sheaths which cover their edges and deprive them for a time of their cutting power.

But it is not in the intestine only that enzymes are found; they are also poured into the blood by the pancreas and probably by the thyroid and other glands. As our acquaintance with the processes of cell life increases it seems more and more likely that the tissue change on which functional activity depends is effected by enzymes, and the truer do the speculations of Van Helmont appear—that life is a process of fermentation.

There can be little doubt that if enzymes in a free state were to circulate through the body they would do much harm, and indeed we may regard this as well-nigh proved in regard to the enzyme of tetanus.

But their action is limited either by their conversion into zymogens or their localization to the cells or tissues where their action is required. This is more readily seen in plants than in animals, and one of the best examples of it is that in germinating wheat.

In the ordinary state of the grain the diastatic ferment is kept apart from the starch by a small layer of cellulose, through which the diastase cannot pass, but during germination another ferment appears which has the power of dissolving cellulose, and by breaking down this dividing membrane it allows the diastatic ferment to act upon the starch, and renders it available for the needs of the growing plant.

Enzymes appear to differ among themselves nearly as much as albumin, albumoses, and peptones. Some are easily separated from the cells in which they exist, while others are so closely united to the protoplasm that their separate existence apart from it has been denied. The yeast plant, for example, yields an invert enzyme which can be extracted with comparative ease, but the enzyme which splits up sugar into alcohol and carbonic acid is so firmly attached to the protoplasm of the cell that it is only within the last few months that it has been isolated by Buchner by the application of enormous pressure. It is probable that the enzymes contained in the cells of animal tissues differ in like manner, and that by the use of similar methods we may obtain a number of enzymes with which we are at present unacquainted.

But it is not merely the products formed in the digestive canal, or in the organs of animals during life, nor even the alkaloids that are formed by the higher plants, that act as poisons. The processes of life are much the same in the lowest microbes as in animals, or in the higher plants, and these microbes, by forming ferments and poisons, give rise to disturbance of function or death in animals. When grown in suitable media outside the body they produce enzymes and poisons, albumoses and alkaloids, and many of them continue to do so after their introduction into the body.

One of the most curious points, in the chemistry of both the higher plants and of microbes, is that they tend to form at the same time a poison and its antidote. In Calabar bean, for example, we find there are two poisons—physostigmine and calabarine, the former tending to paralyze the spinal cord and the latter to stimulate it, so that each poison to a certain extent antagonizes the other. The same condition is found even more markedly in jaborandi, of which the two alkaloids, pilocarpine and jaborine, antagonize one another's action, so that, although pilocarpine generally greatly predominates, it might be possible to get a specimen of the leaf having no action at all although it contained a quantity of alkaloids.

When injected into animals the toxins formed by microbes and the venins of serpents cause the production of antitoxins and antivenins which neutralize their action apparently by chemical combination in somewhat the same way as an acid and alkali, each poisonous by itself, combine to form a comparatively inert salt. But the two components here, like an organic acid and a mineral base, are unequally affected by destructive agencies, and the antivenin may be destroyed, so that the venin again regains its activity.

The conversion of zymogens into enzymes may be compared to the freeing of venins from their compounds, while the conversion of active venins into inert bodies by combination with antivenins suggests that a similar process may occur in the case of active enzymes, by which they may be converted into inactive zymogens.

Perhaps the hypothesis I mentioned eight years ago to my pupil and friend, Mr. Hankin, that the germicidal power of organisms is proportional to their power to produce enzymes, may not be altogether unfounded, and possibly we may discover also that immunity, natural or acquired, is nothing more than an extension to the cells of the tissues generally of a power which is constantly exercised during digestion by those of the intestine and liver.

This problem is one which pertains to all three sciences, and has a most important bearing on practical medicine.

Practical medicine, except when empirical, depends for its advance on physiology, pharmacology, and pathology. A knowledge of the physiology of digestion has led to the satisfactory treatment of dyspepsia by the administration of digestive enzymes, and pharmacological research has enabled us to treat diseases of the circulation with a success previously undreamt of, by teaching us not only how to use aright old remedies, such as digitalis, but also how to apply new ones, such as strophanthus and amyl nitrite, and even to manufacture others, such as nitro-erythrol, which possess the special actions we desire, but are lacking in the drugs we already have. Indeed new remedies, which shall alter tissue change, lower temperature, relieve pain, and procure sleep, are now being made in such numbers that it is hard to keep count of them.

But among all the new gains of practical medicine none are so remarkable as those which we owe to pathology. Time would fail me to speak of the prevention and cure of zymotic diseases, but no less astonishing is the discovery that myxœdema depends on inactivity or absence of the thyroid gland, and can be cured by the administration of its extract, which seems to act as an enzyme on living tissues, so that the heavy, shapeless features of the patient resume their natural expression and the sluggish mental processes become quickened. An exhaustive study of enzymes and their products appears to be the most promising way of advancing our knowledge of both the nature and treatment of disease. Probably more is to be hoped for from an investigation into the nature and properties of those enzymes which are intimately associated with the protoplasm of the cells in the various tissues and organs than even of those which are poured into the blood by glands having an internal secretion, such as the thyroid. For all organs, even those which, like muscles and nerves, are not glandular, have an action on the blood comparable to that of the yeast plant, which modifies the fluid in which it lives by the substances which it removes from or adds to it. It is to a knowledge of the processes which occur in the pro-

toplasm of the cells in the intestinal wall and liver, and of the enzymes by which these processes are in all probability carried out, that we must look for an explanation of the conversion of the poisonous albumoses formed during digestion into innocuous albumins, and of dangerous enzymes into harmless zymogens.

Moreover, it seems to me that it is by researches into the nature and action of the enzymes, not only of microbes, but in the various tissues of the body in higher animals, that we shall learn how the microbes, like the enzymes of the intestinal canal, produce poisonous albumoses, and how the tissues, like the cells of the intestinal walls or liver, convert them into harmless or even protective substances. In this way we may hope to obtain an explanation of toxins and antitoxins, of pathogenesis and immunity, as well as of the nature of diseases unconnected with the presence of microbes, such as diabetes. Twenty-three years ago I attempted to obtain a glycolytic enzyme from muscle, in order to enable diabetic patients to utilize the sugar in their blood. My attempt was unsuccessful, but we may still hope that by other methods we may obtain from animal organs various enzymes, the administration of which may prove as useful in other diseases as the thyroid in myxœdema.

Practical medicine depends on physiology, pharmacology, and pathology, but all three are tending to become more and more subdivisions of the wider and all-embracing science of chemistry. It is to a chemist, Pasteur, that we owe the wonderful development of pathology within the last quarter of a century, and we may fairly regard his fellow-countryman, Lavoisier, as the founder of this science. Men from all countries, and especially from Germany, have aided its development; but it seems fitting that at this congress, in acknowledging our obligations to this science, we should not omit to mention that at its head now stands a Russian, Mendeleef, whose marvellous prescience enabled him to predict the existence of elements which were then unknown, and even to describe their properties more correctly than those who first verified his predictions by obtaining the substances themselves. When we consider that little more than a hundred years have elapsed since the time of Lavoisier, and contemplate the vast benefits which medicine and its allied sciences have derived from chemistry during this time, our hopes cannot be otherwise than great for the centuries to come.

MUSHROOM POISONING

By GUIDO E. GUGLIERI, M.D.

Last February I was called in consultation to see a family of six persons who had partaken of poisonous mushrooms, which resulted in the death of three of the children. I consider it interesting to report these cases from the fact that the symptomatology was unlike that of the usual cases of reported poisoning, and furthermore for the reason that poisoning by toadstools should be more carefully studied by physicians and reported, so that, in view of the uncertainty which exists in the literature on this subject, we may gather more extensive data from which to draw our deductions.

The special mushroom which produced death in these cases was pronounced by botanists to be the Agaricus muscaria, but I suspect there was more than one variety among those eaten; therefore not too much importance must be attached to the above classification.

Case I.—Boy, aged eight; robust; he ate a little over one-half of a medium-sized fungus about six o'clock on the evening of February 24th. He slept well all night and awoke next morning with little disposition to play with his brothers before getting up, as was his custom each morning. When he arose from bed he had a loose passage but complained of no pain. The father noticed that his eyes had not their usual brightness. When dressed he complained of being short of breath and wanted to stay in the open air. The bowels again moved, with more pain. The father, suspecting the mushrooms, then administered castor oil to all the family, which was vomited by them. After this the diarrhœa increased and likewise the griping, but no further vomiting followed the administration of the oil. At three o'clock the boy was feeling fairly well, but quite weak; in the mean time the father had consulted a physician, who gave him some chlorodyne for the boy. During the early part of the evening he was taken with convulsions which increased in intensity, and at eleven o'clock he expired in one of these attacks. I did not see this patient, being called in consultation the next morning.

Case II.—Boy, aged five; robust; he ate the same quantity as the former, and likewise slept well during the entire night, looking dull in the morning; after dressing he went into the yard to get some fresh air, complaining of dyspnœa as his brother had done. After he was given the oil he vomited, which was soon followed by diarrhœa, but he did not complain particularly of pain; during the evening he stated that he felt well, although the father says he had the same dull look that was present during the day. After the death of the first patient he was put to bed, and slept apparently soundly during the night, being awakened only for his medicine. Following the death of the first child, another physician was called in, who advised the administration of two drops of tincture of belladonna every hour; this was given to all the patients during the rest of the night. The following morning the boy on awaking asked for his coffee, which was at once ejected by the stomach, followed by general convulsions. It was at this time that I was sent for and found the boy in the dorsal decubitus, breathing heavily and quickly with slightly livid face. The pulse was very rapid, empty, easily compressed but regular. It was impossible to arouse him: the pupils were contracted and did not react to light: toward the end they dilated widely. The body was dry with the exception of the face and neck, which were slightly moistened with perspiration. It was quite evident that the patient was moribund and after several hours of convulsions he died.

Case III.—Boy, aged ten; robust; ate about one-sixth of a mushroom. During the same evening he slept well, and next morning with the exception of the sickness produced by the oil felt well enough to attend school, where he had a slight attack of vomiting at ten o'clock. During the rest of the day no particular illness was complained of, with the exception of a feeling of lassitude and restlessness. I saw this patient in the morning, thirty-six hours after the ingestion of the mushrooms; at this time there was an expression of extreme fear on his countenance. The pupils were contracted; the head and neck were covered with perspiration: the respirations were rapid and full: the pulse was rapid, full, and regular. There was no vomiting, diarrhœa, or colic. The intelligence was considerably blunted. After a few hours I again saw him and he was then comatose, although when shaken violently and asked if he wished to drink he would answer in the affirmative. The pulse at this time was slower and the pupils were more dilated, but as he was now being subjected to injections of atropine this change was probably due to the drug. His condition for the next fifteen or twenty hours remained the same: there were occasional attempts at vomiting, and there seemed to be a suppres-

sion of urine, which ceased after the application of hot poultices to the loins. The evening of the third day after eating the fungi the boy grew worse; his stupor became more profound, the pupils more dilated, the pulse more quickened, more compressible and irregular, the breathing acquiring the characters of Cheyne-Stokes respiration, and lastly a hiccough developed. At three o'clock the next morning there was a spasm of the lower jaw, which lasted but a few minutes, and then death supervened, the pulse becoming rapidly feebler and irregular just before the end. Death occurred in this case eighty hours after the boy had eaten the mushrooms.

Case IV.—The father, a man of about thirty-eight, strong, robust, and of unusual intelligence, ate by far the most of the mushrooms, having consumed at his dinner nearly two mushrooms. That night he felt a little dull and the next morning on awaking felt more so. However, he overcame this feeling and went out in the morning to get the castor oil, which he, like the others, vomited. He again vomited at eleven o'clock in the morning. During the day he was stupid, but still felt anxious regarding the children. He continued in this state until after the death of the first boy, when he felt so ill that he was obliged to go to bed, attributing his illness to grief at the death of his son. He could not sleep, but yet had a feeling of satisfaction; he realized that his son was dead yet did not care. During the early hours of the morning he attempted to arise but found he could not move except after great effort. His feeling of apathy then gave way to one of great fear for the safety of the children. In the mean while the gastro-intestinal symptoms were becoming more marked, and he was taken with frequent desire to go to stool and slight vomiting. I saw him at this time and found him in a stupor: he was easily aroused and was then able to answer questions fairly intelligently. The skin was moist with perspiration: the pulse small and rapid but regular: the breathing quick, shallow, and noisy; the pupils were slightly contracted. This condition continued for a period of twenty-four hours or more, and then gradually improved, so that in a few days he was entirely well with the exception of an urticaria which developed over the body generally.

Case V.—The mother, aged about thirty-five, robust and healthy. Nervous temperament. She showed few signs of intoxication with the exception of slight diarrhœa and vomiting, with some mental excitement. After the death of the third son she had an attack of hysteria, which soon passed and there was no further trouble. She ate only one-sixth of a mushroom, which accounted for the mildness of the case.

Case VI.—Little girl, aged four: ate about one-sixth of a mushroom: her symptoms were the mildest of all; she had only a little vomiting on the second day and practically no other signs. The treatment was mainly prophylactic in her case.

This is a *résumé* of the cases which it was my lot to have to treat. I presume my readers will be struck, as I was, with the difference in time it took the mushrooms to prove fatal. The second son, who ate about one-half of a mushroom, died in about thirty hours, whereas the younger brother died after eating the same quantity twenty hours later. The eldest son, who ate the same quantity as the little girl and mother, succumbed after eighty hours, whereas his sister and mother were but slightly disturbed. Lastly the father, who ate nearly two entire mushrooms, was rendered quite sick, but recovered after eating nearly four times the quantity that proved fatal in thirty hours in a boy of eight years.

It would be impossible to draw any conclusions from the above figures except what seems to me to be most likely—that there was only one poisonous mushroom in the small lot that was cooked and that this was divided among the boys, the others suffering from the edible fungi being impregnated with poisonous principles in the process of cooking. The study of poisonous fungi and the nature of the poison is one of the most difficult in toxicology. Cases of poisoning by mushrooms are fairly common, especially in winter and spring, but fortunately many terminate favorably even after severe manifestations of toxic action. I consider it unnecessary in this paper to describe the criteria for distinguishing the poisonous from the non-poisonous varieties, for this is necessary only for those interested in the gathering, selling, and cooking of this dangerous article of food. Moreover, I think that if I were to do so I would have a difficult task on my hands, if I am to be guided by what I read in this regard. Dr. R. T. Foster, in an article in *The Boston Medical and Surgical Journal*, says that the signs of differentiation between the two varieties are not well marked: while on the other hand Dr. Charles McIlvaine, in an article in *The Therapeutic Gazette*, states that it is very easy indeed to recognize the edible from the non-edible fungi. Lastly, many of the German authorities claim that all fungi are poisonous, a statement which I consider exaggerated.

However, be this as it may, the facts remain that when we are called to treat people who have been suddenly taken ill and give a history of having feasted on mushrooms, it is our duty to act and act quickly, without delaying to inquire as to the nature of the mushroom partaken of. The poisoning due to mushrooms manifests itself in two ways; the one with marked gastro-intestinal symptoms coming on soon after the ingestion of the fungi and rarely fatal in adults, the other with similar symptoms soon superseded by a narcotic condition frequently ending fatally.

The former cases explain why some consider all forms of fungi as poisonous. Their opinion is based on the fact that many forms of edible fungi have at times caused dangerous symptoms in those who have partaken of them, ignoring whether the mushrooms contained some alkaloid proper to the plant or whether the sickness was not induced by some other accidental conditions developed in them. Mushrooms are substances rich in water, nitrogen, and vegetable albumin, which in the presence of heat and air furnish capital conditions for putrefactive changes giving rise to noxious ptomains which are violent irritants to the alimentary tract in exactly the same manner that meats, cheese, and other articles of food are when spoiled. It is likely also that variations in the soil may affect the nature of edible mushrooms, for it is probable that these have an influence on the products elaborated by the vital activity of the plant, in the same way that certain bacteria become pathogenic only when cultivated in certain special culture media.

The treatment to be instituted in poisoning by this non-muscarine-containing mushroom consists only in allaying the pain, nausea, and diarrhœa, and stimulating the heart with mild cardiac excitants. The form of poisoning which occurred in the cases I have reported was not of this type, but was due to the deadly Amanita muscaria. The poisonous principle is generally conceded to be muscarine, first isolated by Schmiedeberg. Apoigier has prepared from the amanita a crystallizable acid principle, soluble in ether. Leteillier separated an amorphous tasteless substance that he named amanitine. Ponchet, in an article which recently appeared in *Le Progrès Médical*, denies that the active toxic principle of toadstools is muscarine, and claims it to be an albuminous compound similar to the toxins found in putrid organic matter, which has when injected into frogs a physiological action in no way similar to that of muscarine. Muscarine, according to the description of Schmiedeberg, is a colorless,

syrupy mass, lacking odor or taste, easily soluble in water, especially if slightly acidulated, and in absolute alcohol; it forms salts with acids and has an alkaline reaction. Muscarine is present in the dry fungus to the amount of about one-fifth per cent. The symptoms produced by muscarine poisoning are similar to those produced by amanita. I have been unable to find a case of muscarine poisoning reported, but from its administration in animals we see symptoms quite similar to those found in cases in which poisonous fungi have been eaten.

Rademaker, in an article on the toxic action of muscarine, in *The American Practitioner and News*, says, in speaking of the physiological action of this drug, that "after the administration of ten grains of sulphate of muscarine to a dog weighing thirty pounds the symptoms manifested were as follows: Half an hour after eating the food containing the muscarine, vomiting was produced, followed almost immediately by evacuations from the bowels and the passage of urine. The pupils became contracted and the heart's action irregular. The lacrymal secretion and flow of saliva were increased; at the same time the dog had general tremors. The dog completely recovered. The next day the same dog was given the same dose again, with the same symptoms following and complete recovery in eight hours. These experiments prove that muscarine cannot be considered a very powerful poison, but it demonstrates the fact that its action is almost immediate, even when taken with a full meal."

I cannot agree with Rademaker when he says that muscarine is not a powerful poison. He doubtless forgot that much of the ingested poison was eliminated with the vomited matter. Schmiedeberg found that one-thirteenth of a grain of muscarine in the human subject caused myosis, loss of focalizing power, abundant secretion of saliva, flushing of the face, perspiration of the whole body, griping and rumbling in the bowels and a feeling of weight in the head. Moreover, when we consider that the quantity of muscarine in the amanita in the dry state is one-fifth per cent. and that the quantity of mushrooms eaten by the eldest of the three boys that died was so small (only one-sixth of a small mushroom which was rich in water) was sufficient to produce death in eighty hours, I consider it indeed a very powerful poison or else there must be present in the mushrooms secondary poisons of which we have no knowledge.

The treatment of these cases is, as in all cases of poisoning, to empty the stomach if we think that any food remains in this organ and to administer a good purge; next to support the strength of the heart by the injection of stimulants. The drug *par excellence* which is to be used for this is atropine. This is a real antidote to muscarine, having in every respect a physiological action exactly opposite to that of muscarine. The treatment followed in my cases was that pursued and recommended by all toxicologists. Owing to the fact that I saw the patients as late as thirty-six hours after they had eaten the mushrooms, I considered it useless to administer an emetic, and furthermore it was evident from the condition of the patients that the poison had to be combated in the circulation. The patients were immediately given injections of one-fiftieth of a grain of sulphate of atropine and one-sixtieth of a grain of strychnine alternately every hour. The children were given less strychnine in proportion than the adults, but were given the same quantity of atropine, with the exception of the little girl, who, owing to the mildness of her symptoms, did not require very active treatment. After the injections, the pupils dilated widely and the heart and breathing improved, but the coma remained unchanged. The patients were given in addition cracked ice with cognac and seltzer by the mouth. Authorities all agree that fluids by the mouth are injurious, owing to the fact that they favor the absorption of the muscarine, which is very soluble in water. This objection, though, is not to be considered in my cases, for the muscarine had undoubtedly all been absorbed and the administration of water could only do good by favoring the flow of urine and in this way accelerating the elimination of the poison from the system.

Atropine is unquestionably the most reliable antidote that we possess for mushroom poisoning. Comparing the action of muscarine and atropine in the animal body, we find an almost complete physiological antagonism. Why, then, you may ask, were we not more successful in our cases? The reasons are several.

(1) The time which elapsed from the fatal meal to the beginning of the manifestations of toxic symptoms was so great that the poison was undoubtedly all absorbed, and hence emetics, purges, etc., were useless.

(2) The period which elapsed from this time to the injections of atropine brings up the total to about thirty-six hours before the patients received the treatment which might have saved their lives.

(3) The injections of atropine should have been made more frequently and in smaller quantities.

(4) The slow elimination of the poison from the body owing to the suppression of urine.

This suppression of urine is common in cases of poisoning from many other substances, and I have no doubt is caused by the great lowering of blood pressure due to the vasomotor paralysis. That there is a paralysis of the vasomotor system and of the sympathetic in muscarine and many other forms of poisoning, is shown by the livid face, congestion of the conjunctiva, oral and nasal mucous membrane (more marked in other cases I have read of), headaches and delirium, contracted pupils, increased flow of saliva and of perspiration.

The ideal method of treating any case of poisoning in which the toxic substances have already entered the blood would be, first, to stimulate the heart only to that point necessary to overcome the decreasing action of the poisonous drug; second, to hasten the elimination of the poison as much as possible; third, to dilute the poison as much as possible within the body. Regarding the use of cardiac excitants in poisoning-cases, I consider that the greatest discretion is necessary, for at this time the heart is laboring under the greatest disadvantages and the slightest overstimulation may cost the patient his life. It is for this reason I would suggest a change in the method of administration of stimulants in these cases. We are called to see a case similar to those I have described and we find the heart badly affected; we at once inject a fair dose of some cardiac stimulant and the heart in a few minutes picks up its strength so as to beat even more strongly than normal, then in a brief period it again begins to fail: but we do not always dare to give another injection at once for fear of substituting one poison for another. In this way the heart is alternately overstimulated and then allowed to beat on in a weakened condition. The obvious way to correct this would be to furnish the antidote in small doses, but to inject it continuously. The way in which I propose to do this would not only fulfil this condition but would also raise the blood pressure in the arteries and dilute the poison. I would suggest injecting subcutaneously a large quantity of fluid, say six or eight ounces every hour, in which a small triturate of the special stimulant used is dissolved. I would precede this by at least one injection in the ordinary way and then resort to the method I have described.

I have as yet had no experimental or clinical experience with this method, but I hope that some may see enough in the suggestion to try it at the first opportunity that presents itself and report with what success.

[illegible]

KOLLMANN'S NEW URETHRAL DILATOR.[1]

BY FERD. C. VALENTINE, M.D.,

[illegible]

ALL cases of urethritis, acute or chronic, simple or specific, are curable. This assertion is likely to provoke criticism from those who hold opposite views, or who deem "life too short to waste it on chronic clap."

Yet those who, guided by the urethroscope, follow methodical dilatations as developed by Oberlaender and irrigations as popularized by Janet have every reason to controvert both the above opinions. Cases recover more rapidly than by either of the plans of the eminent men cited, and during the treatment none of the concomitants occur as they do in using each method alone.

Irrigations, urethral and intravesical, without a catheter, were not accorded the popularity due them until about eighteen months ago. Indeed it required the persistence of a Janet, a Goldberg, a Brewer, a Swinburne, to persist in the then uncleanly treatment due to faulty apparatus. To-day even a tyro can irrigate the bladder without a catheter, and not spill a drop of the fluid used. I lay stress upon this fact, in the hope of inducing all exclusive specialists to employ the method which has such splendid scientific indorsement as of the eminent gentlemen mentioned. But my purpose now is to take advantage of the present high privilege accorded me of demonstrating a new dilator, which, you will agree, is the most ingenious, as well as the best instrument thus far devised for the purpose.

A few words on the evolution of the dilator may not be amiss in this connection. Oberlaender,[2] to whom the credit of working out the dilatation treatment is due, says: "The purpose of instrumental treatment is to stretch or break hard or soft infiltrates, either with superficial or submucous injury to them.[3] Nothing else can be accomplished by the introduction of metallic instruments of small or large calibre. The very frequent disproportion between the meatus and sounds, especially those over 30 F., and the exceedingly disagreeable sensations produced by their insertion, led my thoughts primarily to a dilator. I worked for a number of years with a spring dilator of insufficient strength; accident then brought Otis' instrument into my hands. In the course of time I gradually developed from it a number of instruments suitable for each zone of the urethra. . . . In 1888, about a year after the publication of my instruments, von Planer, of Graz, also made known dilators based upon the same principle. He now (1894) uses my instruments."

Shortly before Oberlaender published his first paper on dilatation in chronic urethritis, James P. Tuttle, of New York, independently took up the method, with, however, not entirely the same purpose in view. He writes me: "My dilator was made for me in December or January, 1886–87. I used it first as an adjuvant to internal urethrotomy, afterward taking up extreme dilatation, as I became more and more convinced that it was this which cured. The first description I ever saw of Oberlaender's instruments was published more than two years after I had been using mine. I do not know how much earlier it had been published in German. I did not publish my instrument until I had sufficient experience to recommend its use and the cases to show." He first described his dilator in the *New York Medical Journal* for October 3, 1891. The illustration shows that it differs in some essential points from the instruments devised by Oberlaender and Kollmann. Tuttle's dilator is best described in the inventor's words: "The special points of interest in the instrument are its parallel separation over a limited space, its powerful mechanism, its applicability to all portions of the urethra, and its protecting rubber cap."

FIG. 1.—Tuttle's Urethral Dilator.

FIG. 2.—Oberlaender's Straight Anterior Dilator.

To attempt to belittle the modest claims of the ingenious inventor would be to earn just condemnation. An honest difference of opinion, however, may lead to discussion which must be of the desired benefit. On this score I beg to submit to Professor Tuttle the following thoughts on his dilator. If the urethra were a rigid tube, giving firm support to the shaft of the instrument, the dilating blade would exercise that equal pressure, in at least two directions, which is the purpose in view. The branches of the Oberlaender and Kollmann dilator separate equally from an imaginary central line, accomplishing the end sought more efficaciously than could be done by the Tuttle instrument. The advantage of separation over a limited space is not evident to me. As the beneficial effects of dilatation are exerted upon the points of greatest resistance, the unaffected parts are spared compression. Assuming that every operator has the skill to locate exactly the diseased points, it seems to me that limiting the dilatation to them implies a greater frequency of and more prolonged treatment than if an instrument able to dilate the entire urethra is employed.

FIG. 3.—Oberlaender's Curved Anterior Dilator.

[1] Read before the genito-urinary section of the Academy of Medicine, on February 9, 1897.

[2] "Klinisches Handbuch der Harn- und Sexualorgane," Leipzig, 1894.

[3] Tuttle, in an exquisite paper on "Extreme Local Dilatation in the Treatment of Urethral Stricture and its Allied Conditions" (New York Medical Journal, April 13, 1895), says: "The cure of stricture by gradual dilatation is based upon the assumption that a retrograde metamorphosis is set up in the connective tissue, which causes its atrophy or absorption, and the coarctation is thus removed."

The powerful mechanism of the Tuttle dilator is gladly conceded and indeed seems to me the most important feature of the instrument. Its applicability to all portions of the urethra is not so patent. It is readily seen that the Tuttle dilator can well be applied to all parts of the pendulous urethra, when the curved tip would prove rather an impediment. But, if used even at the first portion of the *pars fixa*, it cannot disturb the relations of the region; certainly not an advantage in treatment directed primarily to increasing the lumen. These criticisms, made in that same cordial spirit with which Professor Tuttle favors those whose work he discusses, suffer much in force when his brilliant results with this instrument are examined.

FIG. 4.—Oberlaender's Dilator for Posterior Urethra

Discussion of the Tuttle dilator saves repetition and makes unnecessary a detailed description of the other dilators in use to-day, as far as my knowledge extends.

Oberlaender's almost straight dilator for the anterior urethra was his first instrument on this plan. Its resemblance to the one devised by Otis is at once evident.

Oberlaender's curved dilator, intended mainly for dilatation of the bulbous portion, certainly makes a decided advance over its predecessor, in urethral instrumentation.

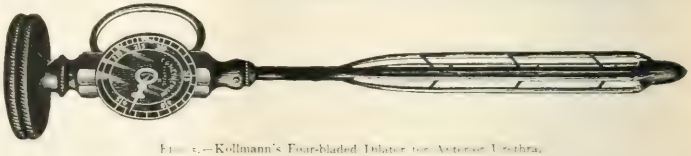

FIG. 5.—Kollmann's Four-bladed Dilator for Anterior Urethra.

Oberlaender's dilator with the Béniqué curve, as its shape shows, is intended for dilatation of the posterior urethra exclusively. The straight blades of the instrument, lying in the anterior urethra, do not expand at all, thus sparing this region unnecessary dilatation.

While the immense therapeutic advance made by these intruments is undeniable, they have their limitations in the fact that they are two-bladed. With a view to hastening the results in the chronic diseases of the urethra, Kollmann devised his four-bladed dilators. His first instrument for that purpose, as its form shows, is intended for the anterior urethra. This was followed, after two years of close study and experiment, by Kollmann's four-bladed dilator for the posterior urethra. But after use of this instrument for some time, it proved to be somewhat clumsy and painful to the patients; at least, so it acted in my hands. This led me to essay designing a better four-bladed instrument for the posterior urethral curve. But before I could even properly formulate my thoughts, Kollmann's genius produced his four-bladed dilator with the Guyon curve, for the posterior and part of the anterior urethra.

This instrument, which I now have the honor of being the first to show in America, has been in daily use for about three months. Experience, covering about two hundred and fifty dilatations during this period, has made me an enthusiast for it. The mechanism is so self-evident that I need only add praise for the ease with which it is inserted, for the exquisite gentleness yet efficacy of its dilatations, for the markedly rapid results it yields, and its surprising painlessness to patients.

The therapeutic value of dilatations, the indications for each instrument, the technique of their employment, have been fully discussed in a paper on "The Treatment of Chronic Urethritis," prepared by me for the Second Pan-American Medical Congress, held at Mexico in November, 1896. I am more than pleased that opportunity still remains to add the description of this instrument to that paper before its publication.

Strangulated Hernia.—The treatment of cases of strangulated hernia after the operation is almost as important as the operation itself. This patient, almost immediately after the operation, was given something by the mouth every hour; only a few teaspoonfuls of stimulant or of fluid food, but still something. These patients suffering from what we may call the asthenic form of strangulated hernia must not be starved after the operation. They are advanced in age, feeble, pulled down by hard work, drink, or chronic organic disease, ill nourished, and now still further exhausted by pain, vomiting, loss of sleep, and fear of death. Often they come to the hospital in the middle of the night, and at once they are subjected to the further shock of the anæsthetic and the operation. Such patients must not be starved, or fed only by the rectum; it is absolutely necessary that we should begin, even a few hours after the operation, to give them small quantities of stimulant and of fluid food by the mouth. —DR. PAGET, *The Clinical Journal*, April 28th.

CHRONIC FOLLICULAR TONSILLITIS.

By W. SCOTT KENNER, M.D.,

BUFFALO, N. Y.,

FELLOW OF THE AMERICAN LARYNGOLOGICAL, RHINOLOGICAL, AND OTOLOGICAL SOCIETY; PROFESSOR OF LARYNGOLOGY, MEDICAL DEPARTMENT, NIAGARA UNIVERSITY; SURGEON IN CHARGE OF THROAT DEPARTMENT, BUFFALO EYE AND EAR INFIRMARY; LARYNGOLOGIST TO THE ERIE COUNTY HOSPITAL; LARYNGOLOGIST TO THE ORPHANS' HOME, ETC.; LARYNGOLOGIST TO THE CHILDREN'S HOSPITAL, ETC.

THE conditions which I am about to describe are not correctly defined by the above title; they are more correctly although not fully described by the term chronic lacunar tonsillitis. Therefore, if you will pardon me, I will try to tell you in as few words as possible just what are the classes of cases which I wish to include under the above title. The conditions are simple and well known to every one, but the symptoms vary greatly in individual cases, and the reflex manifestations produced by them are so varied that I hope I shall be excused for calling your attention at this time to so simple a condition. I wish merely to excite discussion and the citation of cases illustrating some of the peculiar phenomena.

Chronic follicular tonsillitis is characterized by the formation of plugs of secretion in the crypts of the chronically inflamed tonsils. These plugs resemble very much the contents of comedones; are usually about the size of a rice kernel, but vary very greatly in size; they are white or yellowish-white in color and have a very offensive odor, which is brought out by crushing them. They are frequently the source of offensive breath; when crushed, they are found to be of a soft cheesy consistence; they consist of the material discharged from the tonsillar crypts, and are made up of leucocytes, epithelium, chalk, mucus, and the various bacteria, etc., which infest the mouth, among which leptothrix frequently plays an important part. The only chronic condition with which, as you know, this can be confounded is mycosis of the tonsil, in which the plugs are of a more dense consistence and project from the crypts beyond the surface of the tonsil like small cockspurs. These spurs are removed with greater difficulty than the simple plugs, and are found when examined under the microscope to be made up entirely of leptothrix or some other form of mycotic growth which develops very rapidly, the spurs replacing themselves very quickly if removed. The tonsils themselves in which the chronic follicular trouble occurs are often more or less hypertrophied, but some of them are considerably atrophied; in fact, some are so small that they cannot be seen on making a pharyngeal examination until the anterior palatine fold is pulled forward and to one side with a probe, when frequently one or two crypts are exposed filled with very large plugs of secretion; these crypts have very little tonsillar tissue about them, and often in tonsils of much larger size the offending crypt is not found until the palatine fold is pulled aside to expose it. The number of crypts which are inflamed or obstructed varies greatly; in large ragged tonsils the gland is often filled with numerous plugs; small tonsils may have but one or two obstructed crypts. The large tonsils with numerous crypts do not often produce so unpleasant or so marked symptoms as those with less secretion, especially if the crypts which are giving trouble are so located that the secretion is not easily expressed from its bed by the ordinary movements of the throat muscles. The larger tonsils when filled with the secretion, unless during an acute exacerbation, produce only a sensation of fulness in the throat; the patients who have more obstruction to the free discharge of the contents of the lacunæ complain of pain in the throat, pain extending to the ear or chest, pain externally in the cervical region, on one or both sides, fatigue of the muscles of the neck, and some complain of severe neuralgia and various other indefinite reflex phenomena. The plugs do not produce symptoms while they are small, and when they are once expressed from the crypts the symptoms usually disappear until another crop has had time to form. As the masses increase in size, they often cause a swelling at the orifices of or about the middle of the duct just external to the offending secretion; this is especially apt to take place after exposure to cold, after the ingestion of hot food, and a sudden increase of the virulence of the streptococci contained in the secretion may set up an acute inflammation; such acute attacks may last for a day or two, or may end in a regular acute follicular tonsillitis involving a part or the whole of the tonsil, or both tonsils, and this may be accompanied by more or less fever, according to the virulence of the bacteria contained in the inflamed tonsil. Should the tonsil at the same time contain some of the Klebs-Loeffler bacilli such a case would be classed by our boards of health as one of true diphtheria. Patients who are subject to frequent attacks of quinsy are usually subject also to chronic follicular tonsillitis, and destruction of the chronic tonsillar disease will do much to prevent the annual return of these unpleasant attacks.

The upper angle of the tonsil, which is often hidden from view between the anterior and posterior palatine folds where they approach each other to unite in the soft palate, often contains one crypt, sometimes two crypts, with their external openings pointing upward. Such a cavity is not so easily emptied as one which is directed downward, and the secretion remains in the follicle for a long time. When you examine a tonsil in which this portion is producing the symptoms, the patient will exclaim, when this portion of the tonsil is touched with a probe, "That is the place," and if in such a case you separate the sides of the crypt located here the pearl-like pellet of secretion will usually pop out or can be easily pressed out of its bed. Such patients, besides complaining of some dysphagia, will complain of otalgia, or a tickling in the external auditory canal of the corresponding side. If this portion of the tonsil is touched with a hot electrode, either when the tonsil is normal or when it is diseased, the patient will complain of pain in the ear. This is a reflex through the auricular branch of the vagus. I have frequently located the cause of an otalgia in an obstructed lacuna in the upper part of the corresponding tonsil. This symptom is usually accompanied by some dysphagia. Such cases were especially instructive when the patients happened to be suffering at the same time from chronic deafness, and when both they and their physicians considered that the otalgia and the deafness were due to the same cause. This pain in the ear is more familiar in cases of severe acute inflammation in this region of the throat, such as a peritonsillar abscess or quinsy. Only the other day I saw a case with severe pruritus in the external auditory canal, which was relieved by applying cocaine to the upper portion of the tonsil. In a climate such as is found in the region of the great lakes, where all parts of the upper air passages may manifest some evidence of catarrhal inflammation, it often becomes difficult to locate exactly the cause of some obscure throat symptoms. It is often very difficult to say whether the symptoms are due to an obstructed nose, a granular pharyngitis, or to some condition of the pharyngeal, lingual, or faucial tonsils.

The following history of a case illustrates such a difficulty, which occurred to me a few months ago, when the trouble proved to be due to an unsuspected condition of one of the faucial tonsils. A general practitioner, a friend of mine, wrote me as follows:

Read May 4, 1897, at the third annual meeting of the American Laryngological, Rhinological, and Otological Society, at Washington, D. C.

"May I encroach upon your kindness and ask your aid in an obscure case of mine. The patient, a married lady of twenty-five, has had a great deal of trouble with her throat: she was in a church choir a long time, and suddenly her voice began troubling her in sustaining tones, and any exertion of singing, or even talking for any length of time, caused her to have a constant ache and acute burning sensation in her throat, which, in fact, is the condition of the patient at the present writing. I have examined her carefully from time to time, and beyond a condition of relaxation and general congestion I can detect nothing pathological. I have thought it was rheumatism, but rheumatic pains elsewhere have entirely disappeared, while this remains, and both she and I are discouraged. It has been a year since it began, and I have exhausted my remedies without result: what about electricity? I would take it very kindly should you help me out." There was, of course, nothing in this history which should make me suspect the tonsil of being the cause of the trouble. I therefore concluded that she probably was not using her voice properly, etc., and suggested that she had probably been improperly trained in the use of her voice, and that she had some nasal obstruction which he might have overlooked, which would increase the fatigue of using her voice, especially if used in an improper manner. I advised him to use the electricity as he had suggested, together with iron and strychnine, and to enjoin rest of the vocal organs until he had treated her nose if necessary, and until she could procure a better vocal instructor. This treatment, of course, did not help her; no one could make a diagnosis without seeing the patient. In a few weeks she came to Buffalo to see me. At first I could find nothing in the throat which seemed sufficient to cause her symptoms, for besides the loss of her singing voice she complained bitterly of intense pain, neuralgic in character, in the right half of her neck. Besides this, she had a feeling of great fatigue in the muscles of the throat, especially after using the voice. I was much puzzled for a cause of the symptoms. I found her throat about as her physician had described it. She had some granular pharyngitis, and I commenced to cauterize the patches on the posterior wall of the pharynx, and was engaged in the third *séance* of the treatment, when her right tonsil, which was small and perfectly smooth, attracted my attention. I noticed a much distended crypt on the upper surface. I at once plunged my electrode into this opening. The tonsil proved to be simply a small crypt-like organ distended with inspissated secretion, and I opened it with the electrode and destroyed it. After thorough destruction of all traces of the tonsil, which was accomplished with the galvano-cautery in two or three sittings, all the symptoms of pain and fatigue disappeared; her voice improved under proper vocal instructions and tonic treatment.

This is only one of the many cases which might be cited of small diseased tonsils which have been the unsuspected cause of distressing symptoms. A paroxysmal cough is frequently caused by some diseased condition of the faucial tonsils. In children the cough is frequently due to very large faucial tonsils, which by touching other parts of the throat set up an irritation, resulting in distressing and prolonged coughing. When in children the faucial tonsils are not enlarged, the cause of the cough can often be found in the presence of a large amount of adenoid tissue in the vault of the pharynx, but enlarged tonsils are not the only tonsils which are productive of cough. It frequently has its origin in an old follicular inflammation, sometimes in tonsils which are very much atrophied. I once sought for a long time for the cause of a very irritating cough which had persisted for eighteen years. This occurred in a patient over fifty years of age. I found the cause in an obstructed crypt on the posterior surface of the right tonsil; the lacuna was prevented from easily discharging its contents by a partial adhesion between the tonsil and the posterior palatine fold.

Treatment.—A paper has already been presented at this meeting on "Surgery of the Faucial Tonsils," therefore it will be superfluous for me to enter into a detailed discussion of the treatment of these cases. I shall merely outline the principal indications for treatment. The first indication is to open and destroy every pocket or crypt which may form a lodging-place for secretion or particles of food, and secondly, if we accept the teaching that the tonsil is simply a diseased mass, especially in adult life, the only indication for treatment is to remove or destroy all of the diseased mass, to eradicate as far as possible every trace of tonsillar tissue; these two objects may be accomplished in various ways, and the individual case will suggest to the experienced operator the best way to attain his object, the destruction of the tonsil. The conditions of which I have spoken are usually found in adult life; the principal trouble caused by hypertrophied tonsils in children is due to the obstruction which they cause to respiration, and this usually is due more to the accompanying adenoids than to the tonsils, unless the tonsils are extremely large. Tonsillotomy has many opponents among the laity, by whom various reasons are given for their belief that it does harm or no good. Most of the reasons which they give are not the real ones for the failure of the operation to benefit the patient. The first reason for the unsatisfactory result is that the tonsils have been removed, while the adenoids, the chief cause of the obstructed breathing, have been left, a mistake which is often made by the general surgeon in treating these cases. The second reason for failure is that the tonsils have not been thoroughly enough removed to destroy all the diseased crypts, and consequently the patient will still be subject to repeated attacks of acute follicular and supurative tonsillitis; in these cases great masses of lymphoid tissue are left attached to the palatine folds, while only the parts of the tonsils have been removed which projected beyond the folds into the isthmus of the fauces. This demonstrates that all adhesions between the palatine folds and the tonsils should be broken down before an attempt is made to remove them by any method. It is also important that the tonsils of children should be more thoroughly removed than they often are, for thereby all diseases of the tonsil which might occur in adult life may be prevented.

I formerly always used the tonsillotome in removing the glands from children's throats, but lately I have found that a much more thorough operation could often be done with a cold snare in many cases, because the loop of the snare could be passed well in between the palatine folds and almost every vestige of the tonsil removed. In adults, when the offending tonsil is large enough to grasp with the snare, I use it to remove the organ, and the ordinary polypus snare is usually sufficient for ordinary hypertrophied tonsils, such as those I have described. When the tonsils are fibroid in character an écraseur or the galvano-cautery snare might be necessary; for very flat tonsils, which cannot be grasped with the tonsillotome or snare, some other method must be followed. I usually either lay open the crypts with a long sharp bistoury and remove the intervening portions of tonsillar tissue with the cold snare or a pair of cutting forceps, or destroy them by means of the galvano-cautery. The cases which give the most trouble are those in which large crypts are situated in the side wall of the pharynx with scarcely any tonsillar tissue

about them; here the only thing that can be done is to change the whole affair into cicatricial tissue by means of the galvano-cautery. The danger of hemorrhage after the removal of tonsils occurs most frequently in hyperplasia of the tonsil, the fibrous tonsils, a class of cases which it has not been my intention to speak of in this paper.

761 Penn. Street.

WHAT ARE THE FUNCTIONS OF THE RODS AND CONES AND THE PIGMENT EPITHELIUM LAYER OF THE HUMAN RETINA?

BY FRANK P. PRATT, M.D.,

JACKSON, MICH.

The human eye has long engaged the attention of students and specialists. Exhaustive research has been made in the field of anatomy, histology, and pathology of the different ocular tissues in man and in the lower orders of vertebrates; yet there are many problems, around which the searchlight of scholarly minds is being thrown, which have not been satisfactorily explained.

The phenomenon of vision is one of these; particularly so when we consider the part played by the retina, or rather the epithelial pigmentary layer and the layer of rods and cones, in this complex act.

The generally accepted theory is that both the rods and cones are the terminal cells of the optic nerve; that the image of external objects is focussed upon this layer, and that here light vibrations are changed into another kind of motion, namely, nerve stimuli; that certain mechanical and perhaps chemical changes take place in the epithelial pigment layer, and that a peculiarly intimate relation exists between this layer and the layer of rods and cones.

Fuchs says that the place in which the conversion of luminous vibrations into nerve exitation occurs is the rods and cones. I wish to present the following hypotheses:

1st. That the cones alone are the terminal cells of the optic fibres in the human retina.

2d. That the rods are supporting tissue to the cones, their outer segments practically forming a part of the pigment epithelial layer.

3d. That the tenth or pigment layer is that in which light vibrations are changed into nerve stimuli.

A full consideration of the microscopical anatomy of the retina would be impossible here, on account of limited space; reference, therefore, must be made to the text-books of anatomy and histology. Piersol's article on "Microscopical Anatomy of the Retina," and May's on "Photo-Chemistry of the Retina," in Norris and Oliver's work, cover the field very fully.

Assuming, then, that this histological knowledge is in mind, we will review only such salient points as are necessary to make clear the foundation for the propositions above presented.

The retina of the old school comprised the nine innermost layers only, or that part which includes the fibres and terminal cells of the optic nerve, together with the internal limiting membrane. Later research has demonstrated that the epithelial pigment layer also belongs to the retina, and constitutes its tenth stratum. This layer is in intimate relation with the ninth, and, together with the seventh and eighth layers, has no blood-vessels of its own, but receives its nourishment from the same source—the choroid vessels. The rods and cones alike pass through the cribriform external limiting membrane, the rods extending to the "base" of the epithelial cells, where they terminate in irregular "gnawed-off" ends; the epithelial cells sending down protoplasmic processes between the rods and cones to various depths; or this epithelial "base" may be considered as a "disc," which is perforated with cylindrical channels for the reception of the external segments of the rods. Thus the outer rod cell is plunged deeply in the pigmented portion of the epithelial cells. This relation of rods and epithelial processes is maintained uninfluenced by the light stimulus.

The cones also pass outward and terminate in gently rounding ends, which reach little more than half-way to the "base" of the epithelial cell. The cone is not a fixed cell, but under the influence of its normal stimulus retracts, so that the whole cell is nearer the external limiting membrane. When this stimulus is removed the whole cell again advances. This is an important difference, and should be given its proper weight in a consideration of the functions of the rods and cones.

Authorities differ as to whether the terminal cell is connected to the nerve fibre by continuity, or simply by contiguity or approximation. Hosch, however, claims that he "finds in the Golgi silver preparations evidence of direct anatomical continuity between the fibrils proceeding from the base of the cone cell and the processes of the nerve cell." No such continuity has been demonstrated or claimed for the rod.

What proofs, then, have we that the cones alone are the terminal cells of the optic nerve in the human retina? Consider in this light the following facts:

1st. That the cones alone have been demonstrated to be connected directly with the filaments of the optic nerve.

2d. That no such claim is made for the rod; in fact, the base of the rod is known to terminate in a bulb, and approximation is its only relation to the nerve filaments.

3d. That the cone is mechanically irritated by converted light stimulus, as shown by its power of contraction and extension under that stimulus.

4th. That converted light stimulus has no mechanical effect upon the rod; that its close relation to the base of the epithelial cell remains unchanged under its influence.

5th. That the only change noted in the rod cell is that which occurs in the bleaching and reproduction of the so-called visual purple, which has its exclusive seat in the outer segment of the rod cell, and this bleaching appears to be effected by the action of the luminous vibrations themselves, and not by the proper nerve stimulus. Light vibrations as such are not excitors to the terminal cells of the optic nerve.

6th. That the cones alone occupy the position of most acute vision.

7th. That the rods are not necessary to acute and perfect vision.

8th. Because in central scotoma the disease involves only that portion of the retina which has to do with acute vision, namely, the macular region; yet a cross-section of the optic nerve, where it enters the bulb, shows an accompanying atrophy of nerve filaments, which occupy a sector-shaped space, with base out and apex toward the centre, and make up nearly or quite one-third of the total nerve filaments (Fuchs). When we consider what a small part of the retinal surface the macular region occupies and how insignificant numerically the cones of this region are compared with the combined rods and cones of the extra-macular region, it not only adds weight to the belief that each cone in this region has an individual nerve fibre, but also to the fact that each cell element of the extra-macular region cannot have an individual nerve fibre; nor one fibre for seven cells, as estimated by Selzer and Krause. These authorities estimate the cones at 7,000,000. Becker estimates 13,000 in the macula lutea. The rods are much more numerous,

being estimated as high as 130,000,000 by Krause. Selzer and Krause estimate the number of measurable fibres of the optic nerve at 425,000. Now, taking out the 13,000 fibres distributed to the macular cells, there remain 412,000 fibres, to be distributed to 137,000,000 extra-macular cells. If these were distributed to both the rods and cones, there would be 1 fibre to 332 cell elements; if to the rods alone, 1 to 301; if to the cones alone, 1 to about 17. These estimates furnish additional evidence that the cone cells alone receive filaments of the nerve.

9th. That the normal position of the cone is at right angles to the external limiting membrane and the pigment epithelial layer.

That this position can be thus maintained, outside of the macular region, only by appropriate supporting tissue.

In the macular region each cone is a support to its neighbor; therefore no rods are necessary. In the extra-macular region the cones become farther and farther apart toward the peripheral portions of the retina; they can no longer support each other; therefore rods appear, and, with the protoplasmic processes of the epithelial layer and the modified lymph, fill in the intervening spaces. The rods, which in the macular region form a single layer around each cone, gradually increase in number, until, in the region of the ora serrata, each cone is surrounded by three or more layers of rods. The outer segment of the supporting rod, as it dips deeply into the pigment processes of the epithelial layer, thus becomes practically a part of that layer.

10th. That in proportion as the cones increase in number over a given area, vision increases, and *vice versa*. Thus the cones within the macula lutea are many times more numerous than in any other equal space on the retina. Therefore, more terminal filaments being irritated, sight is more acute.

The third general proposition is that the tenth retinal layer in that is which light vibrations are changed into nerve stimuli.

Briefly stated, the tenth layer is composed of a single stratum of hexagonal cells, a view of the inner surface of which shows a beautiful mosaic arrangement, deeply pigmented, except in the region of the nucleus. A vertical section shows the cell to be divided into three parts or zones—the outermost containing the nucleus, and being unpigmented; a middle zone deeply pigmented, sometimes known as the "base" of the cell; and an irregular zone of "indefinite protoplasmic processes," extending between the outer segments of the rods and cones. This pigment is special and peculiar to this layer; it differs from the stroma pigment of the choroid in being crystalline and rod-shaped instead of granular. Under the influence of light these pigment crystals advance within the protoplasmic extensions of the "base" of the cell, between the rods, the migration not being accompanied by the protraction and retraction of the processes themselves.

I present the following reasons for believing the third general proposition to be true:

1st. The pigment epithelial cells increase in size from the region of the fovea, where they are the smallest, to the region of the ora serrata, where they reach their maximum size, thus coinciding with the decreasing number of cones from centre to circumference; so that it is probable that when the ninth and tenth layers are in their normal position each cone points to the centre or nucleus of each epithelial cell.

2d. The peculiar yet significant associated action of the epithelial pigment and the cone cell, under the influence of light stimulus: as the pigment advances within the epithelial processes, the cone retracts, and *vice versa*, their relative positions being little changed.

3d. The position of the cone is strong evidence that the image is not formed upon this layer. Nature is a conservator of forces; then why does she not turn the cones toward the source of light, if this layer is the necessary surface upon which the image is cast, instead of turning them in the opposite direction? In the one position the image would fall directly upon the percipient surface; in the other the light rays pass through the nine different retinal layers to accomplish the same purpose, if the accepted theory is true.

Nature has made no mistake. The cones are turned toward the source of their normal stimuli, but this stimulus is not light vibration, as such, and therefore does not come from the object itself; it is another form of energy. "This is, without doubt, simply another sort of motion, of such a nature as to be transmitted within the nerve fibres to the brain—a property which is not possessed by the vibrations of luminous ether" (Fuchs).

Thus it would seem that "vibrations of luminous ether" must pass unobstructed through the various retinal layers, including the cones, until they are focussed upon the tenth layer, which point is a "murky veil" at the focal point of the normal eye, fixed between the delicate terminal cells of the optic nerve and the choroid coat. It is the ground-glass plate of our living camera, upon which the images in our visual field are spread in all their various colors, and in which, in a manner not yet fully understood, light vibrations are transferred into nerve stimuli, and from which comes the normal stimulus of the ocular fibres.

It is well known that the anatomical and histological arrangements of tissues are not the same in different vertebrates—thus, in the frog rods may predominate in the region of most acute vision; or that rods alone, or perhaps modified cones, may alone be present in others; or that a complete decussation of the optic-nerve fibres takes place in some of the lower animals. Yet this does not warrant us in assuming that the above facts do not hold true in man.

In the words of Fuchs, in speaking of the decussation of ocular fibres: "The only mistake that has been made is in assuming the same condition to hold good for the higher vertebrates also."

It is not claimed here that pigment is necessarily present in order that this change from light vibrations to nerve stimuli may take place; for in albinos, in which pigment is absent, the visual act is accomplished, yet always imperfectly. It is therefore probable that in exceptional cases some modification in the pigment substance takes place, yet always at the expense of perfect vision.

Much has been said about the visual purple or rhodopsin of Boll. Yet when all is said, little or nothing is known of its real utility. We know that it exists exclusively in the outer segment of the rod; that even in the cone cell of the extra-macular region it is not present. That it is not essential to perfect vision is evidenced by the fact that it is absent in the region of the fovea. "Animals that have been deprived of visual purple do not act differently from those which possess it. Frogs, without this visual purple, search for their favorite color, green" (May). In fact, it may act, owing to its position, in common with the elements of the pigment layer in absorbing and transforming luminous ether vibrations into normal nerve stimulus.

Ulcer Grafting.—Skin grafting will not succeed upon an unhealthy surface. Cleanse the surface well for a few days with boric fomentations, slightly abrade the granulations, enough to cause oozing, and then apply the grafts to the abraded surface, where they are held in place by green protective.—GILL.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 43, 45, & 47 East Tenth Street.

New York, August 28, 1897.

THE MOSCOW CONGRESS.

THE Twelfth International Medical Congress, of which we publish in this issue the first part of our special cabled report, was successful far beyond the expectations of those who had watched the course of preparation for it during the past two years. The committee on organization had much more to contend with than any similar committee of an international congress, most of its trials being due to the peculiarly paternal character of the government under which its members lived. When it was first announced in Rome that the next congress would be held in Russia it was stated that the committee was not authorized to announce the place of meeting, for the designation of the city to be thus honored must be left to the Tsar. When the preliminaries of the plan of organization were published, the English-speaking world was antagonized by the dropping of English from the list of official languages. This drew forth a vote of protest from the American Medical Association, and may have been the reason why the British Medical Association decided to meet this year in another part of the world, as far as possible from Moscow. No sooner had this error been recognized and corrected than the news came that the efficient and popular secretary-general of the committee, Professor Erismann, had for political reasons been expelled from Russia. At the same time Hebrew physicians began to inquire how they would be treated if they attempted to go to the congress, and it was intimated that they would be turned back at the frontier. After more or less discussion and protest it was finally announced that on this occasion no discrimination would be made against any physician desiring to take part in the proceedings of the congress, because of his race or religious belief. These difficulties and many others which could not have come up elsewhere, and which would seem to have been enough to chill the ardor of the most enthusiastic committeeman, were all met and overcome. And the Moscow congress, in its externals at least, for we cannot judge of its scientific rank until the reports of the section work have been received and studied, has passed into history as one of the most successful of the twelve.

The general addresses were all of a creditable character, although no new facts of serious import were brought forward—nothing, indeed, of the startling and sensational character of Koch's memorable address in Berlin seven years ago. This is perhaps just as well, for true science needs no theatrical setting, and it would have been much better if the German investigator had not been forced by his government superior to make a premature announcement of his discovery in order to add *éclat* to the tenth congress. The orators in Moscow, at least those who did not deal chiefly with orrhotherapy, as a rule contented themselves with restating old facts, some, as Virchow, reiterating the beliefs to which, in somewhat modified form, they still clung despite the assaults of the neopathologists. Virchow's was a touching figure at the congress—this wonderful old man and indefatigable worker in many fields, a physicist, a publicist, a linguist, and a pathologist, equal to the first in each of his chosen spheres of activity. All the world will add with one voice its fervent *No* to those with which the congressists met his suggestion that this was perhaps the last congress at whose deliberations he would be able to assist. The young man of seventy-six summers was well inspired when he chose as his theme "The Continuity of Life," and his hearers did well to remind him that he was wandering too far from his subject.

The entertainments provided for the visitors were on a most lavish scale, and are even yet not at an end. While one party has been taken to see the beautiful scenery of the Caucasus, another has gone to the Crimea, and still another is enjoying a series of fêtes organized in honor of their guests by the hospitable citizens of the northern capital. The method adopted by the municipality of Moscow for showing its appreciation of the honor of harboring the congress was unique. Instead of opening a public building for a reception and spending a large sum for decorations, and for eatables and drinkables, the memory of which would pass away almost as quickly as the headaches they had occasioned, the council determined to establish a prize for medical work, to be awarded at each recurring congress. The sum set aside for this purpose was about 16,000 rubles, and the value of the triennial prize will be $1,000. Thus will the memory of these sober city fathers ever be kept green.

The announcement that the next congress will be held in Paris at the time of the international exposition is only what was anticipated. The French have long contended for the honor of entertaining the congress and it is fitting that they should do so during their year of jubilation.

From the report of the proceedings of the principal sections which our special representative has secured for us, and which will be published in future issues, the readers of the MEDICAL RECORD will learn of the work of the congress and will be able to judge whether it was such as will contribute to the onward progress of scientific medicine.

RECIPROCITY IN MEDICAL PRACTICE.

THE action of some physicians of New York and other large cities who visit the summer resorts of New England and elsewhere and there follow their profession is always severely criticised and gives rise to much

heart-burning among the resident medical men. They contend that these city doctors have no right thus to combine business with pleasure and take the bread out of their mouths. We find in the *Atlantic Medical Weekly* of July 17th some correspondence and editorial comments on this subject, in which the case is presented very fairly. It would appear that the fault lies chiefly in the laxity of the State laws, and that so long as a visiting physician conforms to the law no valid objection can be made to his practising, but that if he does not fulfil the necessary regulations then the authorities, if notified, must act. As to the hardships resulting to the local practitioners from the lack of reciprocity our contemporary says: "Granting all the premises regarding the *raison d'être* of the law, it is notably unfair that one State should admit to all the rights of the profession while barred from gaining an equivalent for its own citizens, unfair that New York men may come to New England and replenish their purses while recuperating their health, while New England men who may spend a few months in the metropolis attending perhaps post-graduate studies are denied the privilege of practising." All this is very true, but surely at least to a certain extent the remedy is in the hands of the resident practitioners. Why should not the doctors of New England follow the example set them by the native medical men in Italy in their present crusade against foreign physicians, and induce their legislatures to debar others from practising medicine in their States unless they can be allowed the same facilities in New York or in the other cities from which the visiting doctors may come? Of course the inequality in the standards in the different States is the chief obstacle in the way of reciprocity, and until a uniform course and a uniform method of conducting examinations are introduced, it would seem that the difficulties are almost insuperable. However, after all the solution of the problem lies in State legislation, and that is where the remedy should be sought.

BICYCLE RIDING A REMEDY FOR ASTHMA.

Dr. Marcet, of London, is strongly of the opinion that bicycle riding is very beneficial in cases of asthma, he even goes further and says that it may act as a cure. If this opinion should receive practical verification, the already popular exercise will gain yet another impetus.

Dr. Marcet says: "If asthma is a form of mountain sickness, and if that distressing affection of high altitudes can be cured by training for the exercise of climbing, why should not asthma also yield to the training of the respiration carried out by practising the respiratory movements wanted to carry the tidal air through the lungs? Of all means of training respiration I think cycling is the best. When a person first takes to cycling exercise it will be found, especially on going uphill, that the breath is wanting, the heart beats uncomfortably, and the legs tire; but after some training these discomforts all disappear; nothing will be thought of hills to ascend, the heart has become perfectly comfortable, all breathlessness has disappeared, and the legs will no longer feel any fatigue. Cycling exercise first of all increases the depth of breathing, and that without fatigue, as the respiratory movements are automatic; at the same time it will accustom the rider instinctively to take in at each respiration the volume of air required to aerate the blood and to eliminate a fixed proportion of CO_2, leaving in the circulation the precise balance of CO_2 compatible with health. Persons who do not care for cycling out of doors can take the same kind of exercise at home by means of a dummy cycle consisting of an iron wheel driven by pedals, the resistance of the wheel being so contrived as to simulate bicycle riding. A strap carried partly round the rim of the wheel can be tightened at will by the rider, thus increasing the labor and recalling the effort of riding uphill. My experience of the results of this treatment is unfortunately limited to only one person; in this case it has proved eminently successful. This person took to bicycle riding about three years ago for pleasure, and in very great moderation for the first two years. He observed last summer that the attacks of asthma to which he was subject had become very much fewer. The tightness and wheezing which occurred every night have now entirely disappeared."

VERMINOUS PERSONS IN ENGLAND.

In England it is proposed to deal by the strong hand of the law with those who are troubled with parasites. The *Hospital* for July 17th has an article under the rather repellent title of "Verminous Persons." It would appear that a bill has lately been introduced into the British House of Commons for the relief of verminous persons, and that in order to avoid discussion of the female-suffrage bill, which was the next on the list, a flood of small wit was let loose upon the bill for the relief of verminous persons, merely to kill time and prevent discussion of the other bill. The *Hospital* gravely rebukes the House of Commons for its unbecoming levity on the subject, and if the accounts given in the *Hospital* are true the matter is certainly past a joke. According to our contemporary, the "verminous persons' bill" is a most necessary measure, and one that would add greatly to the comfort of the poorer classes in the metropolis and in other large towns in Great Britain. It is said that the tenements inhabited by these classes are infested with vermin to such an extent that it is almost impossible to obtain in them a satisfactory night's rest, and in consequence hundreds of men may be seen sleeping on warm days in the parks for the reason that they are unable to sleep in their lodgings on account of the lively pulex and the bloodthirsty cimex. It is difficult to say whether the pest of mosquitoes from which so many people in places outside of New York City suffer is worse than the vermin pest of the English cities. The mosquitoes while they stay are perhaps more venomous and their favors are more impartially distributed, but by way of compensation their season is limited, whereas in Great Britain the "verminous persons" are verminous the year round.

News of the Week.

Navy Department, Bureau of Medicine and Surgery, Washington, D. C.—Changes in the medical corps of the United States navy for the week ending August 21, 1897. August 14th.—Assistant Surgeon F. L. Pleadwell detached from the *Texas* August 17th and ordered to the *Nashville* August 19th; Assistant Surgeon W. M. Wheeler detached from the *Oregon* August 23d and ordered to the Mare Island navy yard for duty in connection with the *Marietta*. August 20th.—Assistant Surgeon D. H. Morgan detached from the *Monongahela* and ordered to the *Cincinnati;* Surgeon A. G. Cabell detached from the *Monongahela* and ordered home to be ready for sea.

The Risks of Travel in Far Countries.—The accident-insurance companies in England do not permit their policy holders to run off when they will to wander in the wilds of New York or Montreal. The *British Medical Journal* announces the fact, which it thinks may be of interest to the members of the association who intend to be present at the meeting in Montreal, that though life-insurance companies permit policy holders to travel in Canada and the United States, an extra premium is charged by accident-insurance companies. The impression seems to be that we shoot only to wing and not to kill.

The Fourth Congress for the Study of Tuberculosis will take place in Paris during the week beginning July 25, 1898, under the presidency of M. Nocard, of the Alfort Veterinary School. The following questions will be discussed: The value of sanatoria as prophylactics and as a means of treating tuberculosis; serum and toxins in treating tuberculosis; use of *x*-rays in diagnosing tuberculosis; the *x*-rays in treating tuberculosis; the success of prophylactic measures in combating animal tuberculosis.

The Plague is reported to be increasing again in the district of Poonah and in the city of Bombay.

Typhoid Fever is reported to be epidemic in Milan.

Trouble in Oklahoma.—The new governor of Oklahoma Territory has appointed a homœopathic physician president of the territorial board of health. This action has naturally aroused the regular practitioners of the Territory, and they are endeavoring to have the appointment revoked.

Homœopathy at the University of California.—The directors of the Hahnemann Hospital College in San Francisco have petitioned for affiliation with the University of California, and a counterpetition has been presented to the regents by the regular faculty of the medical department of the university. At a meeting of the regents of the university held August 10th both petitions were heard, but the final vote will not be taken till the next meeting, on September 7th. The main argument of the homœopathic school is that not to allow it to come into the State University would be taxation without representation. The members of the regular faculty were supported at the hearing by several good speakers, including a delegation from the Medical Society of the City and County of San Francisco, by petitions from the surgeons of the army and navy stations in San Francisco, the local medical societies, and the medical societies of Sacramento and of Los Angeles, and by vigorous letters from Dr. Donald McLean, of Detroit, formerly professor of surgery in Ann Arbor, and from Dr. C. L. Bard, president of the California State Medical Society.

The International Congress of Neurology, Psychiatry, Medical Electricity, and Hypnology.—The first session of this congress will be held at Brussels from September 14th to 19th, under the presidentship of Professor Verriest, of Louvain. The general secretary is Dr. Crocq, of the Molenbeek Hospital, Brussels. Among the subjects for discussion will be the surgical treatment of epilepsy; the pathogeny and treatment of exophthalmic goitre; reflexes, muscular rigidity, and contracture; general paralysis; psychosis and dreams; the semeiological value of electrical reactions of muscles and nerves; the therapeutical value of high-frequency currents; the therapeutical value of hypnotism and suggestion; and the question of criminal suggestions, their origin and actual state.

Obituary Notes.—Dr. George R. Kauffman died at Chambersburg, Pa., on August 13th, at the age of fifty-six years, in the sequence of an attack of hemiplegia.—Dr. George Y. Lehr died at Philadelphia on August 18th from carcinoma of the stomach. A surgical operation was performed for the removal of the growth a year ago, but recurrence took place. Dr. Lehr was born at Gratz, Dauphin County, Pa., May 13, 1842, and was graduated from Jefferson Medical College in 1863. He has lived in Philadelphia for thirteen years.—Dr. Edward W. Kitchel, of Newark, N. J., died at the Roosevelt Hospital in this city on August 25th, in consequence, it is said, of injuries received in a railway accident. Dr. Kitchel was twenty-seven years of age. He was assistant instructor in normal histology at the College of Physicians and Surgeons, New York.

The Late Dr. John J. H. Love.—The following minute was adopted at a meeting of the visiting staff of the Mountain Side Hospital, August 16, 1897:

"No words can express the loss which the Mountain Side Hospital has sustained in the death of Dr. Love, nor is it possible so to construe language as to give the measure of our personal loss in the death of our beloved leader.

"Filled with the courage and self-sacrifice that are born of high purpose and unselfish broadmindedness, and always willing to prefer the wellbeing of others to his own, he gave freely of his time and substance to the hospital.

"Its good name was as dear to him as his personal honor, and from his clear and comprehensive mind came most of the suggestions by the adoption of which the enterprise has been successfully carried on. Without Dr. Love it would have failed; with him, it has achieved an enviable measure of success and usefulness.

"We can no longer enjoy his friendship, his guidance, his counsel, or his sympathy, but we have the brilliant example of his noble life and of his devotion to the best interests of this hospital.

"Richard C. Newton,
"E. M. Ward,
"H. B. Whitehorne,
"*Committee.*"

Colored Woman Physicians.—Dr. Cornelia Kahn, of Cleveland Springs, N. C., referring to a statement that Dr. Emma Wakefield, of Louisiana, was the first colored woman to graduate in medicine, says that the Woman's Medical College of Pennsylvania has been graduating colored women for years. "One, the wife of a minister in Philadelphia, has been practising with success for at least fifteen years. This spring, a colored woman physician, Dr. Brown, passed the State examination with more credit than her dark brothers, and better than some of the white candidates. She is now serving as resident in the hospital for colored people in Charleston, where they have also started a training-school for nurses."

The Adelaide Hospital Trouble. — Drs. Leith Napier and Ramsay Smith, formerly of London, who sold their services to the lay managers of the Adelaide (South Australia) Hospital to take the places left vacant by the former medical board, are doubtless rather sorry now that they did not remain at home. They have not been recognized by their colleagues since their arrival in Adelaide and now they have been cast out at home through a sentence of expulsion from the British Medical Association. While one may be permitted to look with equanimity upon the infliction of punishment for dishonorable actions, it is yet difficult to see how the culprits in this case have committed an actual crime or have done anything legally "infamous." The scramble for hospital appointments which have been vacated by colleagues under pressure from their lay masters is not regarded with pleasure by disinterested onlookers, but if every man who had gleefully taken a brother's place were expelled from his medical society there would be a sad thinning out indeed.

German University Students.—The number of matriculated students in twenty-one German universities during the summer semester of 1897 was 30,932, and of hearers 1,519, of whom 207 were women; students of theology, 4,326; of law, 8,368; of medicine, 8,232; of philosophy, 10,006. There was a marked decrease in the number of students of theology and medicine, and an increase in that of students in the philosophical department, especially in philology and natural science.

A Department of Public Health in Great Britain.—The announcement has been made that when Parliament reassembles it will be moved in the House of Commons "That in the opinion of the house it is desirable that a department of public health be constituted, and that the same be under the charge of a responsible minister having a seat in Parliament."

Secretary of the Interior Ullóa of Costa Rica.—The present secretary of the interior of Costa Rica is Dr. Juan J. Ullóa, who studied medicine in this city and served upon the house staff of St. Vincent's Hospital. As a member of the international executive commission of the first Pan-American Medical Congress, he was the author of the resolution creating the sub-commission on Pan-American quarantine. He is not only a leading medical practitioner of that country but one of its most potent political factors.

"A Cheerful Fact for New York City."—Under this heading an esteemed but somewhat east-winded contemporary remarks that "a statistician catering for the good-will of the Greater New York says that for the six deaths every fifteen minutes there are seven births. Unfortunately, however, the births are largely from that class in the community which is of least benefit to the city." And so, we would apologetically add, are the deaths.

Dr. Max Einhorn has been requested by the faculty of the Post-Graduate School to give special courses next autumn and spring on the newer methods of diagnosis and treatment of diseases of the stomach.

A Town Without a Doctor.—The wonderful discovery has been made that only a short distance from New York City exists a town which has no resident physician. This town is North Bergen in New Jersey. The township authorities had been notified by the State board of health to appoint a town physician, and when they set about doing so they found there was no medical man, except a veterinary surgeon, living in the place. The salary attached to this important office is $50 per annum.

Hospital Enterprise.—A hospital in Omaha is distributing broadcast a catchy circular, which reads in part as follows: "Accident insurance is a good thing. Insurance against ordinary sickness is a better thing. Both in one is the best thing. Do not wait until sickness or accidents come to you before taking out a membership certificate entitling you to free admission, bed, board, nursing, medical and surgical care in case of accident or sickness in the Methodist Hospital of the Omaha Hospital and Deaconess Home Association of the Methodist Episcopal Church. A two-edged sword cuts both ways, and accomplishes its mission in either direction. So does your membership fee. If you have occasion to use the hospital as a member, you have the first right to accommodations, above any other class of patients, and you will be most tenderly cared for. If the Lord spares you in perfect health, your money will assist the institution in caring for some one else not able to pay. It thus becomes a sweet charity whose fragrant memory will follow you all your life." The cost of membership is $10 a year in advance. The payment of $250 in advance makes one a life member entitled to continuous free treatment for himself or, "if the Lord spares him in perfect health," for some one else of whom Providence is not so careful.

Clinical Department.

EIGHT INTESTINAL PERFORMATIONS FROM PISTOL BULLET; OPERATION; RECOVERY.

By J. F. BALDWIN, A.M., M.D.,

COLUMBUS, OHIO,

PROFESSOR OF SURGICAL GYNÆCOLOGY, OHIO MEDICAL UNIVERSITY, GYNÆCOLOGIST TO PROTESTANT HOSPITAL, ETC.

THE following case is worthy of report, since few cases of more extensive injury to the intestines with recovery have been recorded:

April 25, 1897, T. W., aged twenty-one, a student at Delaware College, accidentally shot himself in the abdomen with his revolver. The bullet, of thirty-two calibre, entered the abdomen four inches below the umbilicus and two inches to the right of the median line. As nearly as he could tell, the bullet entered at right angles to the surface. The accident occurred at five o'clock in the afternoon, and he was seen within a few minutes by two physicians. At this time he was suffering from the effects of a good deal of shock. He was at once given a hypodermic injection of one-quarter grain of morphine with atropine, and whiskey was given internally. At eight o'clock the injection of morphine was repeated. I saw him at 11 P.M., in conjunction with his physicians, Drs. Seamans, Murray, and Vogt. At this time his general condition was excellent. His pulse was somewhat accelerated, varying from 84 to 108 per minute, but of good strength and volume. He was free from pain and expressed himself as feeling entirely well.

Notwithstanding his excellent condition, I took the ground at the consultation which followed the examination that from the direction apparently taken by the bullet we could scarcely imagine the bowels to have escaped injury. Even if there were no injury to the intestine, an exploratory incision would not materially increase the risk, while if a perforation existed it would almost certainly prove fatal if left alone. The other physicians present concurred in this opinion, and when our view was explained to the patient he promptly acquiesced. The young man was the son of a surgeon, Dr. J. L. Wylie, of Ripley, Ohio, and had himself studied medicine one year.

With the aid of my assistant, Dr. Chapman, and the physicians above mentioned, the operation was commenced as soon as the preparations could be completed. The incision was made so as to include the wound. The first loop of bowel noticed was brought up into the incision and passed through the fingers until a perforation was found. This was carefully closed with a double row of Czerny-Lembert sutures, fine iron-dyed silk being used. The surrounding area was carefully cleansed and the bowel returned, while more was brought into view. In this way eight perforations of the small intestines were found and closed, and three perforations of the mesentery. There had been no hemorrhage of any moment. The perforations were all within about three feet of the ileo-cæcal valve, the last being about an inch and a half above the colon. The peritoneal cavity was carefully cleaned and the incision closed except at a point where a gauze drain was inserted, so as to give drainage in case an opening had been overlooked or a leak should occur at any point. The operation was completed at 2 A.M., and the patient put to bed in good condition.

The after-treatment of the case was attended to by Drs. Murray and Seamans until the arrival of Dr. Wylie, twelve hours after the completion of the operation. Thirty-six hours after the operation I changed the gauze drain for a small piece inserted just through the incision; this was allowed to remain forty-eight hours longer, when it was removed and the opening closed. The bowels were opened by cathartics on the fourth day. Convalescence was absolutely uninterrupted, the highest pulse rate being 88 and temperature 100° F. At the end of three weeks the patient resumed his college work, and a week later called on me at Columbus.

No attempt was made to find the bullet, which was doubtless lodged somewhere in the muscles of the back. In case its presence should ever make trouble, it can be located by the *x*-rays and easily removed.

The presence of the drain necessarily left a somewhat weak place in the abdominal wall, but if a hernial protrusion should occur at this point a secondary operation would be a very simple matter.

The case is of interest as emphasizing the importance of making exploratory incision in cases of abdominal injury from gunshot wounds, without waiting for symptoms of hemorrhage or of peritonitis to develop. It also shows that with care in the technique even most extensive injuries of the intestines may be recovered from.

SUBMAXILLARY ADENITIS WITH APPARENT INCIPIENT LYMPHADENOMA.[1]

By EDWIN R. MANSON, A.M., M.D., LL.D.,

SYRACUSE, N. Y.

ADENITIS, or inflammation of a gland, with or without suppuration or caseation in scrofulous subjects, has long been fairly well understood. But lymphadenoma, which consists in its first stage of "a mere hyperplasia," and "subsequently of fibroid induration" (Gowers), when not arrested in its incipiency, though described by many, from Malpighi (1669) to Murchison (1870) and later, appears even now to be but imperfectly understood. And a complication of the two conditions, as apparently occurred in a case that recently fell under my care, must, I think, be very rare. I have seen only two other cases, and they were not apparently complicated with submaxillary adenitis; in neither case did the patient live long enough for the process to pass on to induration, suppuration, or caseation.

The subject in this case is a man, sixty-two years of age, farmer, who in childhood had some sort of abscess or swelling about the face or neck, left side, leaving no visible scar that I could discover. Two or three near relatives are said to have died from wasting abscesses. He chewed and smoked tobacco, but was otherwise temperate. After a slight attack of grippe, lasting about a week, during which he was seen by two physicians, neither of whom appeared to have defined his disease, there appeared an almost painless swelling which commenced with slight tenderness in the left submaxillary gland; this swelling rapidly extended to the sublingual and lymphatic glands, and all the structures and tissues of the left side of the face and the entire neck from ear to ear, so as to produce an enormous distention devoid of noticeable pain or tenderness. It was at this stage, after one week of illness, that I was called to attend him, the swelling having increased, I was assured, one-half during the preceding twenty-four hours, almost obstructing respiration, deglutition, and speech, thus presenting the gravest possible symptoms, with the fearful prospect of speedy dissolution, but attended by little or no pain or tenderness.

Called at such a crisis, my first inquiry was as to the possibility of any poison having been taken into

[1] Read before the Syracuse Academy of Medicine, June 22, 1897.

the mouth that might have irritated the left submaxillary gland, which was slightly tender from the first, I learned. But this elicited only the fact that tobacco had been used quite freely, by chewing and smoking; and this fact, together with the evidence of a light attack of influenza attended by a loss of appetite, coated tongue, a bounding pulse, such as I have rarely if ever witnessed before, led me to the conclusion, in the absence of other causes, that nicotine had poisoned the left submaxillary gland and irritated the adjacent lymphatic glands and tissues, and together with the poison of the grippe had led to the apparent incipient lymphadenoma, which was threatening a rapidly fatal termination by apnœa from pressure upon the larynx, trachea, or respiratory passages.

The prominent symptoms in this case were the enormous distention from ear to ear, under the jaws, in front of the neck, and of the left side of the face, with difficult respiration, a bounding pulse, difficult speech, an anxious expression of countenance, and slight tenderness of the left submaxillary gland on pressure under the lower jaw. The remaining symptoms, catarrhal, coated tongue, loss of appetite, lame neck, and slight cephalalgia, were apparently from the grippe, as I viewed the case.

From erysipelas it differed in not being attended by redness; from an ordinary inflammation, in the absence of pain and tenderness, which were slight and manifest only in the left submaxillary gland under the jaw, and from all other conditions, except perhaps snake or septic poisoning, in the rapid extension and development of the swelling.

From all the facts connected with this case, it was my opinion that the grippe predisposed to the hyperplasia which followed, the submaxillary gland being poisoned, inflamed, and narcotized by nicotine, so as to deaden the pain, as it passed on to inflammation and suppuration without pain, all the tissues being thus relaxed, accounting for this supervening apparent incipient lymphadenoma with the attendant threatened suspension of respiration, deglutition, etc. For while under the treatment which I adopted and followed out, no more distention or swelling occurred, at one time, the tenth day of my treatment, while the respiration and speech appeared improved, the patient declared himself unable to swallow for about twenty hours, the sublingual glands became tense, and the surface assumed from the chin to the sternum an erysipelatous appearance. This I attributed to the passage of pus from the submaxillary toward the surface. And this was probably the case, for two days later, the twelfth day of my treatment, the pus made for itself a painless opening nearly opposite the middle of the lower jaw of the left side. The pus came out in a stream, materially lessening the swelling and distention of the parts. The pus was thick, yellowish, and had a slight odor, as might have been anticipated in such a case.

The prognosis in simple uncomplicated adenitis, attended or not by caseation or suppuration, may not be very unfavorable when properly treated, though liable to be of protracted duration. But when complicated with incipient lymphadenoma, as it appeared to be in this case, the danger is very great at best, and especially if not attended to in season. In all cases of lymphadenoma, even in the incipiency if involving the neck, and later, if passing on to induration, involving the spleen, attended or not by caseation, or possibly in scrofulous subjects suppuration, a fatal termination is to be feared. Strangely enough the two cases that I had seen in consultation before this, already referred to, both of which terminated fatally very soon, were clearly produced by nicotine, as was verified by the physicians attending them.

The treatment I pursued in this case was general and local, the general consisting of sulphide of calcium, two grains, morning and evening, to lessen pus formation; one or two cathartic pills daily to clean the tongue; sulphocarbolate of sodium, a grain and a half, with three drops of tincture of nux vomica every six hours; and alternating with this a grain and a half of cinchonidine for the antiseptic and tonic effect, with such liquid nourishment as could be swallowed, and a warm foot bath at evening to favor perspiration.

Locally, removing a cold bread-and-milk poultice, I had a clean white flannel brought under the swelling and up over the sides of the face so as to cover it, tied with tapes over the head so as to make pressure on the swollen parts. Under this I had applied every six hours a strong solution of chloride of ammonium (tepid), except over the region of the submaxillary gland, where I substituted ichthyol, one part to about three of glycerin. And this was continued till the erysipelatous appearance occurred under the chin, when a folded linen, wet in a tepid solution of sulphate of iron, about an ounce to a pint of water, was kept on that part under the flannel and a solution of iodide of potassium over the gland, about two drachms to the ounce of water, till the pus discharged two days later, the fourteenth day of my treatment and twenty-first of the disease. Then the ichthyol was again applied over the region of the gland about the opening, and a poultice of bread and milk was applied and renewed every six hours.

While it is claimed that of "two-thirds of the cases of lymphadenoma no cause can be traced" (Gowers), it is said that it may commence with an "irritation in the submaxillary gland," as in this case, and, extending, may "encircle the neck beneath the lower jaw." But I do not find a parallel to this case in the painless suppuration of a submaxillary gland attended by a rapid hyperplasia, filling the neck from ear to ear, devoid of both pain and tenderness. And yet this case, with almost painless submaxillary adenitis, with suppuration, was apparently one of hyperplasia, constituting the incipient stage of lymphadenoma, while the two fatal cases referred to were without submaxillary adenitis, as appeared.

Finally it remains to be seen whether this case of apparent incipient lymphadenoma complicated with submaxillary adenitis must necessarily pass on from the hyperplasia to the formation in the lymphatics of "tissues similar to those observed in the glands," enlargement, induration, etc. (Roberts), or if the submaxillary adenitis with the drainage of suppuration, early treatment, and no very strong predisposition may not perhaps temporarily and possibly permanently stay or avert the consequences of this semimalignant disease. The abscess healed in about a week, and the fulness and induration have diminished up to the present, it being now the eighth week.

318 Madison Street, Paterson, N. J.

Cholelithiasis.—In considering the question when to operate Dr. Carl Beck (*New York Medical Journal*, May 8th) says: "In summing up, I would therefore advise the operation as follows: 1. Whenever the diagnosis of acute cholecystitis is made, cholecystotomy should be performed without delay. 2. Cholecystotomy should also be performed in chronic hydrops of the gall bladder. 3. Whenever acute colicky attacks in the region of the gall bladder, combined with fever, return for a second or third time. 4. Whenever jaundice is present for more than four weeks. 5. In gallstone ileus. 6. In all obscure cases when inflammatory symptoms resembling peritonitis turn up in the region of the gall bladder, exploratory laparatomy is indicated."

THE TREATMENT OF TAPEWORM, WITH REPORT OF CASES.

BY J. C. CHAMBERLIN, M.D.,

Any one who is privileged to examine and prescribe for a large number of people daily will not infrequently meet with a case of tapeworm. This distressing affection seems to be almost entirely confined to womankind. In fact I have not seen a single case of tænia saginata or solium in a man and my histories are all furnished by women. This is not strange, when the report of the military surgeons of the French army for ten years showed only one case in every thirty-six thousand men. I will not attempt to discuss the natural history of tænia or describe the familiar ribbon-like shape of the worm.

The diagnosis is often made by the patient before she presents herself; and again cases exist which have been treated for dyspepsia, anæmia, and many other disorders for a long time.

The symptoms are not well defined, though intestinal disorders, with or without pain, salivation, vertigo, loss of flesh with great increase of appetite, are the most common ones. The imagination in woman may vary the symptoms in many ways after once the presence of the worm is known.

The treatment pursued in the following cases I have found to give much satisfaction. It contains nothing new except in the combination.

Case I.—Miss A—— had complained of pains in abdomen with attacks of nausea and vomiting for the past two months. Emaciation and loss of strength had been rapid. She had been taking iron for her blood. After a brisk cathartic several links of tænia were found in the stools. Strict orders as to diet were then given. For one and a half days she was allowed only two cups of tea with toast. At the end of her fast she received a half-ounce of magnesium sulphate with two glasses of water; early the next day half an ounce of castor oil; about two hours later, after numerous stools, she took the first dose of the following mixture, followed by another an hour later, until all had been taken:

℞ Spir. chloroformi . . ℥ j
Ol. terebinthinæ,
Oleoresinæ aspidii . . . . . ℥ ss
Glycerini . . . . . q.s. ad ℥ ij
M. S. ℥ iij. q. h.

The stools after the administration of the castor oil contained several links of the worm, but not until the above mixture had blinded him did he let go of the lining of the intestine with his suckers, when the head and twelve feet of the worm were captured. This was no doubt a tænia solium.

Case II.—Mrs. B—— had had dull pains in the abdomen, constipation, and diarrhœa at intervals for the past six months, with increased appetite. She imagined all sorts of things after the discovery of her tapeworm, which she made herself. After the same treatment as outlined in Case I. she passed a worm exactly twenty-one feet in length. There had been no return of her trouble for over a year.

Case III.—Baby, two years old. The mother said that when the child was one year old it passed several feet of a worm. When I saw the child at its home in March, 1896, I gave it castor oil. Latter it passed ten feet of worm connected. In the morning I gave:

℞ Ol. terebinthinæ,
Spir. chloroformi,
Aspidii . . . . . ℥ ss
Glycerini . . . . . ℥ ss
Sig. ℥ i. q. h.

In the evening the child passed eleven feet more, as was ascertained by careful measurement. If the child had not been a strong one the above dose might be considered large. Again I anticipated that much would be vomited up, which was the case. There has been no return of trouble as yet.

Case IV.—Miss G——, December, 1896. For the past three months she had had nausea and vomiting at times. A physician had washed out her stomach, which gave temporary relief. She had vertigo, much nervousness, lumbar pains, frequent urination, and many other reflex symptoms. She was very fond of rare meat and had for some time past eaten a good deal of it. When first seen she said she had worms and that they were always dropping from the rectum. These worms proved to be the joints of the tænia. I gave fifteen minims of oleoresin aspidium every two hours, with the result that a large number of segments were passed. Two weeks later after another dose of aspidium she passed one worm exactly 5.3 metres (or 16¼ feet). Three months later she applied again for treatment. This time I used the mixture as prescribed in Case I., with the satisfaction of recovering the entire worm. By careful measurement it was found to be 8.2 metres (26½ feet) in length and almost intact. There has been no return of trouble for past seven months.

In the preparation of the patient there are certain things, as described in Case I., which must not be overlooked, for on these depends the success of the medicine. In order to find the head and smaller portions, a good deal of care must be exercised in the manner in which the stools are received and examined. A good routine practice is to have ready several pieces of cheesecloth, one of which is to be stretched over a receptacle. As soon as one evacuation has taken place, put another cloth in its place, spreading these cloths with contents on sheets of newpapers for examination. It is only thus with great care that all parts may be washed and saved, and the head may then often be discovered.

[illegible]

A CASE OF HODGKIN'S DISEASE COMPLICATED BY PULMONARY TUBERCULOSIS.

BY CHARLES H. LEWIS, M.D.,

[illegible]

The disease of many names, but perhaps best known to-day, in English-speaking countries at least, as Hodgkin's disease, was first systematically described by Richard Hodgkins[1] in 1832. His data were drawn from seven cases, extending over a period of nearly six years. Three or perhaps four of these cases in clinical history and autopsy closely resemble tuberculous adenitis; in two there seems no doubt that tuberculosis was the etiological factor.

A quarter of a century later Samuel Wilks[2] described five cases with the characteristic appearance of glands and spleen. Two of these cases presented such marked evidence of pulmonary tuberculosis at autopsy, that the diagnosis admits of considerable doubt. He classed the five, however, in the same category with Hodgkin's cases, and christened them all with Hodgkin's name. Wunderlich, Billroth, and Trousseau later described the morbid conditions, and each dubbed the disease differently—all appellations, however, being more or less descriptive of the dominant lesions. The course of the disease since its recognition in 1832 has run suspiciously close to tuberculosis, and the lines of differential diagnosis in many cases have been invisible to the naked eye of any but the reporter. Leukæmia is excluded by the

[1] Medico-Chirurg. Transac., London, 1832.
[2] Guy's Hospital Reports, Series 3, vols. ii. and ix.

microscope, and to that instrument it seems to me we must occasionally appeal in order to exclude a tuberculous gland infection.

In 1892 Professor Duplay[1] presented a case of Hodgkin's disease, complicated or associated with tuberculous adenitis. So far as I am aware this is the only case recorded as combining both diseases, although some histories might justify a diagnosis of either or both, according to the predilection of the reporter. The following case appears worthy of record, mainly on the ground of differential diagnosis.

L. P——, female, married, of Italian birth, was admitted to Columbus Hospital, August 20, 1896. She had been in this country sixteen years. Family history irrelevant, except that a brother is said to have died of "bronchitis." The previous history discloses no syphilitic, tuberculous, or malignant tendency, and is otherwise immaterial up to six months prior to admission, at which time, while pregnant, the patient noticed "some swellings in the neck." These swellings appeared soon after moving into a new house, the walls and floors of which were quite damp. Later she suffered some abdominal and back pains. Two or three months subsequent to the neck swellings similar swellings appeared in the axillary and inguinal regions. About this time she gave birth to a seven-months' child. After her confinement the swellings took on a very rapid growth, the back and abdominal pains increased; she says she became very pale and lost flesh and strength. A persistent and exhausting cough appeared about three weeks before admission; expectoration was scanty and from description without significance.

On admission the patient was weak, emaciated, rather anæmic, and complained chiefly of abdominal pains with more or less general tenderness. The cervical glands in front and behind, while not greatly swollen, on account of the emaciated condition stood out prominently. They were quite uniformly enlarged, about the size of a chestnut, symmetrically arranged, and extended along the sterno-cleido muscles from the lower jaw to the clavicles. The parotid and submaxillary glands partook of the general enlargement. The suboccipital glands, somewhat smaller, ran from the scalp to the ribs behind. Some of these glands were rather soft, but by far the greater number had a hard, smooth feel; they were not adherent to the skin or to each other; none seemed cheesy and none contained pus.

The axillary, epitrochlear, inguinal, and apparently the mesenteric glands adhered to this general description, except that all appeared of hard consistence. None was sensitive.

The spleen was enlarged, not painful.

The heart appeared healthy, rather rapid in action.

Lungs: Prolonged expiration over left apex; no râles or other abnormal physical signs were detected. Temperature, 102.4° F.; pulse, 120. Urine turbid; specific gravity, 1.012; acid; albumin one per cent. by volume; quantity normal. Microscopical examination negative. Blood count showed some diminution of red corpuscles and no leucocytosis; hæmoglobin, eighty per cent. Sputum scanty, muco-purulent; no tubercle bacilli found.

I ordered arsenious acid, one-thirtieth grain, t.i.d., to be gradually increased.

Repeated examinations of sputum were negative until August 28th, when tubercle bacilli were detected. At this time more of the neck glands had a softer feel —some almost cheesy, and one fluctuated. The other glands were apparently unchanged. Legs œdematous; abdomen distended, somewhat tympanitic, and containing a moderate amount of fluid.

September 1st, general condition progressively failing. An epitrochlear gland removed for examination.

September 9th, still more of the cervical glands had rapidly softened and appeared tuberculous. Bacilli in sputum. The epitrochlear gland removed on the 1st inst. showed no bacilli or tuberculous structure, but proliferation of lymph cells with increase of connective tissue. No marked leucocytosis.

On September 10th death took place by gradual exhaustion.

Temperature ranged from 100° to 120° F. during stay at hospital.

Autopsy by Dr. Farquhar Ferguson, twenty-four hours after death: Rigor mortis not marked. Poorly nourished. Œdema of lower extremities. Thorax: No adhesions; one ounce of dark-colored fluid in right pleural cavity. Heart shows cloudy swelling. The left lung is œdematous; has a small tuberculous nodule at apex; localized pleurisy in lower lobe due to a small infarction. Right lung œdematous, otherwise normal. Bronchial glands enlarged and cheesy. Liver, nutmeg. Spleen greatly enlarged. The gastric, hepatic, retroperitoneal, and mesenteric glands are all enlarged, from the size of a pea to a horse-chestnut, and of hard consistence. The mesenteric glands alone are fused together and form irregular masses, varying in size from a hen's egg to a large orange. A large mass of agglutinated glands partially covers the intestines in front. Right kidney shows cloudy swelling. Left kidney has capsule somewhat adherent, is contracted, and contains bands of connective tissue with evidences of chronic diffuse nephritis.

Microscopical examination of the lymph nodes shows proliferation of round cells. No invasion of other tissues. The cells seem to be crowded out by redundant new connective tissue, thus agreeing with Snow's[1] description. Spleen shows same condition. Kidneys present clusters of round cells throughout cortical portion.

I have recorded the autopsy notes rather literally and included all points in them which seem to bear directly or indirectly upon the disease. I have done this because cases of Hodgkin's disease are not frequently met with and autopsies still less. According to the reports for the past year of eighteen hospitals in this city, out of over seventeen thousand cases strictly medical there were but six cases of Hodgkin's disease. Of these six cases three were discharged "improved," one "unimproved," one has no record, and one, reported above, died. Stephen Mackenzie[2] has reported two cases with autopsy.

In the clinical history exposure to a damp atmosphere is the only apparent etiologial factor. The disease seemed to receive fresh impetus after the confinement, thus resembling a case mentioned by Gowers,[3] where the malady lay dormant during a pregnancy, but advanced with redoubled speed after delivery. The association of Hodgkin's disease with the tuberculous infection is chiefly interesting as duplicating Duplay's case, which, so far as I know, is unique in the literature of the subject. It is to be regretted that the cervical glands, which in their later manifestations, to the eye at least, certainly resembled tuberculous structures, were not examined for bacilli. The tuberculous nodule in the lung, however, with the bacillary infection of the sputum, makes the tuberculous element of the case positive. The other symptoms with the autopsy findings clinch the diagnosis of Hodgkin's disease.

Arsenic in increasing doses seems to be the only remedy available. Karenski[4] reports four cases, with

three recoveries; one of the latter subsequently died of phthisis, a fact which may throw doubt upon the diagnosis. Rosenberg[1] followed a case six years without finding any curative effect in arsenic. Dreshfield[2] reports two incipient cases cured by arsenic. Mackenzie's cases were uninfluenced by arsenic and suprarenal extract. In the case reported not the slightest temporary benefit from the arsenic was noted.

28 West Sixty-First Street.

Society Reports.

TWELFTH INTERNATIONAL MEDICAL CONGRESS.

Held in Moscow, August 19, 20, 21, 22, 23, 24, 25, and 26, 1897.

(Special Report by Direct U. S. Cable to the Medical Record.)

GENERAL SESSIONS.

First Day—Thursday, August 19th.

The opening session of the congress was not held in the Grand Theatre, as was originally intended, since it was feared that the hall would be too small to accommodate the immense assemblage, and accordingly the meeting was called together in the Military Manœuvre Hall, a large armory, over five hundred feet in length, which serves excellently for the reunions. All the various bureaus of the congress have also been established in the same building. The Chamber of Commerce, an almost equally large building, is to be utilized for all the public functions of a strictly social character, and is admirably adapted to this purpose. Moscow is crowded with physicians and their families, conservative estimates placing the entire number of visitors, physicians with their wives and daughters, at fully ten thousand. The fears which had been entertained and freely expressed that the railroads would be unable to transport the great crowds converging to Moscow from all points on the frontier were found to be groundless, for the accommodations were ample. The customs regulations were found to be no more vexatious than they are everywhere; the officials on the frontier and everywhere on the route were most obliging, and the passport formalities caused no trouble to any one. Indeed, there is no word but of praise for Russian courtesy and Russian hospitality. Shortly after one o'clock the Grand Duke Sergius stepped forward, and in a few formal words declared the Twelfth International Medical Congress opened.

Address of Welcome.—After the applause following this announcement had died away, Hospodin Dylanov, the minister of public instruction, delivered a brief address of welcome, couched in what Virchow and others of his hearers, who were competent to judge, pronounced most classical and finished Latin. He spoke of the great obligation of all the members of the congress, the Russians especially, to the Tsar, whose unbounded liberality alone had made it possible to bring together this great assemblage in the heart of Russia, for without not only his consent, but his active and personal support and aid, this congress could not have been held in this place. He bade all his hearers welcome to Moscow and to Russia, and expressed the earnest hope not only that the scientific labors of the meeting would be productive of great good to humanity and of added renown to the distinguished men who assisted at the congress, but that all here assembled would enjoy to the utmost the moments of relaxation between the meetings; if they did not, it would, he was sure, not be the fault of the citizens of Moscow and of Russia, lay and medical.

President's Address.—Professor Sklifosovsky, the president of the committee of organization, then spoke. Moscow, he said, greeted joyfully this brilliant assembly of most eminent medical authorities who had gathered there from all parts of the civilized world, even from Eastern Asia and from distant America, North and South. There was no longer, he continued, a wall between Russia and the rest of Europe, but the former was as open as the plains which his hearers had seen after crossing the frontier. To-day Europe is united as it never was before; the east and the west are drawing together and becoming as one in the bonds of a common civilization. It is only now that Europe is beginning to recognize its debt of obligation to Russia for protecting it from the incursions of the barbarians. For ages the Slavs stood on the outskirts of civilization with their faces turned to the hordes pouring toward the west and threatening the very existence not only of the Slavs themselves but of the peoples of the western lands as well. In this long conflict Russia, in order to face the foe, stood with her back to the rest of Europe, and so the latter came to regard her as a race apart and not as of the family of nations. In consequence of her isolation and of the necessity she was under of first redeeming her land from the Tartars and then reuniting its severed parts, Russia had long remained behind the rest of Europe in culture and the arts of peace, but she was now hastening with giant strides to take her place in the front ranks, shoulder to shoulder with the other nations of Europe and America. With the strength of an unexhausted race she had been able to accomplish in a portion of a century what it had taken other nations three centuries to perform. This was not said in a spirit of boastfulness but in one of confidence and of dignified assertion. The medical men of Russia were now ready to co-operate with those of all the world in furthering the uplifting of their beloved science.

An International Language.—Continuing, Professor Sklifosovsky said that the one great obstacle to medical progress was the want of a common medium of communication between the men of science of different nationalities. Nowhere was this almost fatal lack so fully realized as in Russia. The great mass of Russian medical literature was a sealed book to western peoples, and few outside of the country had any conception of the enormous amount of scientific work that was being done there. Russians recognized that their language was too difficult ever to become universally known to westerners, and they were therefore the more keenly alive to the necessity of the adoption of some international speech. He hoped that this would be one of the useful works of the present congress. He would suggest the appointment of a committee to draft a preliminary agreement which should be laid before the next congress for consideration.

Report of the Secretary-General.—Prof. W. K. Roth, of Moscow, the secretary-general of the executive committee of the congress, then presented his report. His first and most pleasing duty, he said, was to thank in the name of the congress, His Imperial Majesty, the Tsar of Russia, the "High Protector" of the congress. Without his magnificent liberality the meeting would have been impossible. The Russian members of the congress, he continued, have withdrawn, wherever necessary, to yield their places on the programme of the sections to the foreigners. In the name of the committee he would crave the indulgent pardon of all for the delay there

[1] Berlin. klin. Wochensch., 1895.
[2] Med. Chron., 1895–96, vol. iv.

had been in the distribution of railway tickets and in publishing details concerning matters of interest to intending visitors. Their only excuse was that they feared to promise too much and were therefore obliged to wait for the necessary authorization, and, as everybody knew, the unwinding of red tape is a slow process. He was able to report the attendance of 7,300 members in Moscow. Of this number more than 3,500 were from Russia, 800 from Germany, as many from Austria, 400 from France, 300 from Italy, 300 from England, 120 from the United States, 30 from Mexico, 10 from Japan, 4 from China, and the rest from the less populous countries of Europe, South America, and the East.

The Moscow International Prize.—Prince Gallitzin, the mayor of Moscow, then greeted the members of the congress on behalf of the great municipality which it was his honor to represent. He announced that the city of Moscow had desired to express in some appropriate manner its appreciation of the great honor that had been bestowed upon it by its selection as the place of meeting of this greatest of congresses, and it had decided to establish a prize of 5,000 francs, to be awarded at each international congress, for all time to come, to the person who in the interval since the preceding congress shall have done that medical work which shall be deemed of the greatest benefit to humanity.

Addresses from National Delegates.—Short addresses were then delivered by delegates from the various countries represented at the congress. General Kohler, surgeon in the German army, said he brought greetings from his gracious master, the German emperor. Peace was the watchword of the times, peace in order that mankind, under the leadership of the medical profession, might wage war against the common enemy, disease. The enormous strides that medicine has made in recent times is shown by the fact that morbidity and mortality from disease are now less than one-half what they were only two decades ago. This address had something of a political turn, and whenever the names of the two emperors were mentioned the speaker was interrupted by the cheers which he evidently expected. He concluded with "God bless the Tsar," and his words brought the audience to their feet with a thunder of cheers. Other representatives who spoke were von Ziemssen for Bavaria, Gussenbauer for Austria, Sir William MacCormac for Great Britain, Thayer of the Johns Hopkins' University for the United States, Dujardin-Beaumetz for France, Hlawa for Bohemia, Kocher for Switzerland, and Haga for Japan. The latter said that he had been authorized to invite the next congress to assemble in Tokio, and he could assure his hearers that they would meet with a warm welcome should they consent to honor Japanese medicine by an acceptance of the invitation which it was his pleasure to extend to them. Professor Hlawa, of Prague, spoke in Bohemian and was loudly and enthusiastically cheered by all those present of Slavic stock. Dr. Dujardin-Beaumetz, medical inspector of the French army and director of the sanitary service under the minister of war, received the greatest ovation from the Russians present, exceeding that given the German representative, in recognition doubtless of the popularity of the Franco-Russian alliance. Hearty cheers also greeted Professor Kocher, of Berne, but this was of course devoid of political significance and was an evidence simply of his personal popularity.

Invitation to St. Petersburg.—The Mayor of St. Petersburg then spoke briefly, saying that he had come from his own city to Moscow expressly to invite all the members of the congress to visit the northern capital after the labors of the meeting were over. Moscow was, indeed, the heart of Russia, but Russian hospitality could not be confined to the heart alone; it extended to the head as well. If his hearers would come they should come as guests of the government and of the municipality. The railway transportation would be free of all charge, and many fêtes in honor of the congress had been arranged for.

Honorary Presidents.—The announcement was then made of the honorary presidents of the congress. These were: Germany—Virchow, Leyden, Ziemssen, and Waldeyer; Austria—Gussenbauer, Hlawa, and Rudiger; Great Britain—Stokes, MacCormac, and Simpson; United States—Senn and Thayer (Billings, it was announced, would have been one of this number had he not been absent); Spain—Robert; France—Lannelongue, Le Dentu, Grasset, and Pinard; Italy—D'Antona, Bottini, and Lombroso. The name of the latter was greeted with prolonged cheers. A recess of five minutes was then taken before the beginning of the scientific work of the congress.

The Continuity of Life.—Prof. Rudolph Virchow, of Berlin, delivered the opening address, taking for his subject the continuity of living matter. Life, he said, has no other origin than from life itself, and this is one of the truths which the labors of pathologists and biologists of the present century have established beyond the possibility of doubt. For long many men of acumen and true scientific minds were inclined to doubt the unbroken continuity of life and to regard spontaneous generation as possible if not actually probable. This theory is, however, dead, and dead beyond the possibility of resurrection—a result which we owe to the labors of many earnest investigators, conspicuous among whom stands the grand figure of Louis Pasteur. The rôle of chemical action in the processes of life or of its continuity has also been found to be less important than it was at one time supposed to be. Life is in the cell. He who speaks of serum as a vital force apart from cells is wrong. The grand truth of cellular succession may be assailed in the future as it has been in the past, but it will never be thrown to earth: it will shine through all the long years of the twentieth century, few if any of which, the venerable speaker said in a half-regretful voice, it would be his privilege to see. This might be his last congress (cries of "No, no!"), but whether it was or not, his earnest hope was that the final mystery of life might be solved and its solution proclaimed at some future congress. If it ever is to be solved, solved it will be by the united labors of the biologist and the pathologist; it is in their laboratory that the key will be forged which shall unlock the door that still holds us back from a full knowledge of the processes of life.

The Sclerogenic Treatment of Surgical Tuberculosis.—Professor Lannelongue, of Paris, delivered the second general address, in which he developed at length the method for some time advocated by him for the cure of local tuberculosis. Resection of tuberculous joints was, he said, a measure of much utility and for a long time was the best we had for the arrest of this destructive process, but at best it was a makeshift. It was a mutilation and in so far a confession of defeat by the surgeon. Furthermore, it was not always possible to embrace all the diseased tissue in the area operated upon, and then relapses were almost sure to take place. Injections of antiseptic substances had been suggested and had been actively urged by some enthusiasts, but practical and extensive trials had demonstrated their inefficiency. Theoretically they ought to destroy the tubercle bacilli and put an end to the disease, but practically they did no such thing. He had conceived the idea of building a wall within the tissues, enclosing on every side the diseased part, and so shutting off the pathological focus from any communication with the healthy structures in the neighborhood. Very numerous clinical and experi-

mental facts had been gathered to demonstrate the value of this method. By injecting irritating substances deeply into the parts surrounding the diseased centre on every side he was able to cause the production of an envelope of fibrous tissue enclosing the tuberculous focus. These irritating injections, besides leading to the production of fibrous tissue, excited an afflux of leucocytes to the part, whose phagocytic action contributed powerfully to the destruction of the pathogenic agents of the disease. The speaker referred to the careful and convincing experiments of Nocard, who had demonstrated by them that the tubercle bacilli, when enclosed by this artificially produced sclerotic zone, were all killed in from six to eight weeks.

Relationship of Physiology, Pharmacology, Pathology, and Practical Medicine.—Dr. T. Lauder Brunton, of London, delivered an address with this title (see page 296).

Reception to the Congress.—In the evening a reception was given to the members of the congress and their ladies by the medical men of the city. It was held in the Chamber of Commerce, the immense galleries of which were thronged by a concourse of more than ten thousand people.

Second Day—Sunday, August 22d.

The second general session was opened at 2 P.M. on Sunday.

The Next Congress.—The announcement was made that the next international congress would be held in Paris in the summer of 1900. Professor Lannelongue was appointed president of the organization committee, and Dr. Chauffard, professeur agrégé in the Faculty of Paris, honorary secretary-general. This announcement was received with prolonged cheers.

Etiology of Progressive General Paralysis.—Prof. v. Krafft-Ebing, of Vienna, then delivered an address, taking as his subject a consideration of certain of the etiological factors of general paresis of the insane. In order to obtain a clear understanding of these factors, he said, it would be necessary to review the conditions of life in the latter half of the century which is now so rapidly drawing to a close. Unless we pause a minute in our onward rush and look back fifty or a hundred years, we cannot realize the change that has occurred. The struggle for existence has become much more severe than it was; competition is becoming more and more active, and this competition is not only between the individuals in one community, one country, or one continent, but all the world is engaged in the struggle. The steamship, the railway, the telegraph, have brought distant countries in contact with each other and made them rivals in the fight for existence. One result of this is that people are being driven more and more from the country into the crowded centres of population, individual effort is vain, and success comes only by means of combinations of capital and of labor. The vital tension has become extreme, and the mass of mankind is struggling now, not for ease and comfort, but for very existence. This strain has become so exhausting in its effects that men are driven to artificial means of relief, to nerve stimulants such as alcohol, tea, coffee, and tobacco. The result of all this overwork and worry and stimulation is seen in the nervous heredity with which so many of our time are cursed. General paralysis is an end-of-the-century disease, the predisposing cause of which is this nervous overtension, the exciting cause of which is syphilis.

The undoubted etiological rôle played by this disease is shown by many facts. In the first place we see that the proportion between the sexes is the same for sufferers from syphilis as it is for general paralytics, namely four men to one woman. General paresis is more common among men of the upper classes, such as army officers, well-to-do merchants, bankers, and the like, who are among the least circumspect in their sexual relations, while it is very rare among the clergy and among women of the upper classes. The principal objection thus far urged against this theory has been that it is not possible always to obtain a history of syphilis in cases of general paralysis. But the rich statistics of the Vienna General Hospital show a still greater proportion of patients with unmistakable tertiary lesions from whom absolutely no history of syphilis could be obtained than of general paralytics from whom no syphilitic history could be obtained. Nine general paralytics in Vienna, who were without any syphilitic history, were recently inoculated with syphilitic virus, and although they were under daily observation for a period of six months not one presented the slightest syphilitic manifestation. It is highly improbable, if not actually impossible, that these nine persons would have shown themselves refractory to the action of the syphilitic virus had they not acquired an immunity through a previous attack. The modern struggle for existence contributes to the frequency of general paralysis not only by predisposing the nervous centres, but also by making syphilis a more common disease. The necessities of modern life cause late marriages, and this enforced celibacy of the younger generation leads to an increase in prostitution. Indeed, civilization and syphilization have come to be correlative terms. The remedy for this deplorable condition is to be found in education, moral as well as mental. Young people must be warned in season, and their teachers must not be content with preaching abstract morality—it is the concrete that appeals to youth. The young must be told of the dangers, proximate and remote, of an unbridled indulgence of their appetites; they must be counselled to moderation in work, to the avoidance of worry, and the consumption of alcohol should be limited as far as practicable. Especially during the growing period our boys and our girls should be watched over and trained up to lives of sobriety—it is at this time that the foundation of a sound constitution, bodily and mental, must be laid.

Classification and Surgical Treatment of Acute Peritonitis.—Dr. N. Senn, of Chicago, then delivered an address with this title (see p. 289).

The Plague.—Dr. Metchnikoff, of Paris, had selected this as a timely subject for discussion at the present time. He described Yersin's plague bacillus, and said that the existence of spores could not be doubted, for an explanation of the many cases of infection through clothes and other fomites after months of desiccation was otherwise impossible. The bacillus itself is extremely delicate and is most easily destroyed. The speaker then described the method of antitoxin manufacture as employed by Roux at the Pasteur Institute in Paris, and explained why this serum when practically tried in India had proved inefficacious. Because of the fear of causing a spread of the disease in Europe, the thirty horses inoculated in Paris in order to procure antitoxic serum for use in India were inoculated with dead cultures. That this was the true reason for the failure of Yersin's tests was shown by the fact that the serum employed in China, which was obtained after inoculation with living cultures, was curative. Thus the mortality of the Chinese cases in which the serum was employed was only seven per cent., while that of the Indian cases was forty-nine per cent. After Yersin arrived in India he made use of living cultures in the manufacture of antitoxin, but his ill luck pursued him, for no sooner had he got everything well started, and had

gone away again, than the chief veterinarian of the laboratory died of pernicious malaria, and those who were left in charge did not conduct all the stages of the manufacture properly. Nevertheless, the serum, poor as it was, was better than nothing. The mortality of plague when untreated is eighty per cent., so that its reduction to forty-nine per cent. was a decided gain even if not a perfect result and not what was anticipated. There is now being made, however, an antitoxic serum of great strength from living cultures which is undoubtedly efficacious in conferring immunity and in curing the disease in its early stages. Recent reports from India declare that the protective immunizing power of this serum is now greater than is that of the serum prepared after Haffkine's method. Inoculations with this serum are devoid of all danger, and produce absolutely no reaction, and the protective influence of the antitoxin is fully as lasting as is that of Haffkine's serum. This, the speaker continued, is an undoubted triumph of orrhotherapy, and establishes the principle of preventive inoculation on a foundation which can never be shaken. That at least some specific diseases can be prevented and cured is a fact that cannot be gainsaid at the present day by any but the most blindly sceptical. A general employment of this protective serum would guarantee the civilized world against an invasion of the plague. It would be too much to hope for the stamping out of the disease among the millions in Asia, where the pest has its habitat, but it would be feasible to inoculate every one coming from infected regions to Europe and other parts of the world and so prevent the spread of the disease.

The speaker closed with an eloquent peroration, recounting the obligations of the peoples of all lands to men of science. The contentions of scientists, one with another, sometimes excited the scorn and contempt of the ignorant, but there is going on here as everywhere a struggle for existence, and the law of the survival of the fittest is as inexorable in its action here as elsewhere throughout the universe. Medical selection, indeed, exerts a most powerful influence over natural selection. It is through rivalry, through criticism, perhaps even through the aspersions of the jealous and the envious, that truth is brought to light and firmly established. The discoveries of recent years in medicine have increased the span of life, and the therapeutic secrets which have been wrested from nature herself are now finding wider and wider employment to the advantage of all, of the poor as well as of the rich, of the millions in distant India and China, as well as of the more cultured inhabitants in Europe and America. This science of the closing years of the nineteenth century is greater in its humanitarian aims than was dreamed of by its early votaries, and who can tell what the twentieth century will reveal? The one desire of the speaker, his earnest hope, was that this work for humanity would continue and would prosper, as it must in these times of union and mutual encouragement of medical men and scientists in all the countries of the world.

The Mutual Relations of Pathology and Therapeutics.—Dr. Robert, of Barcelona, delivered the next address. The cell, he said, is the unit of being. Every function is dependent upon the integrity of the cell, upon its condition of nutrition, and upon its power of reaction against external influences. Pathology consists in the study of disturbed cellular life, of the disturbed relations between the nucleus and the protoplasm of the cell body. The more we study cellular pathology and the greater reliance we place upon its teachings, the more certain is our progress toward the goal of a rational and effective therapy. The treatment of disease must have for its object a rearrangement and a rectification of the disturbed relations between the cells and between the different parts of each cell.

Man, however, is more than a mere cellular congeries; he is a being endowed with certain powers of resistance against influences which threaten his well-being or his very existence. Disease is not dependent so directly upon the action of any specific micro-organism as it is upon an increased organic susceptibility. The mystery of disease is still a mystery, and it has not been solved as yet by any of the facts of bacteriology or pathology. One man is affected by disease, another exposed to the same influences escapes unscathed. A neoplasm which is to-day benign in its appearances may to-morrow assume an entirely different aspect and take on all the characters of malignancy. Why is this? We cannot yet answer. The human organism reacts as a whole to the assaults of disease, and not by the isolated action of any individual cell or group of cells. A specific infectious disease is warded off or overcome, not by phagocytosis alone and not by the special chemical properties of the blood serum alone, but it is conquered by the organism considered as an entity.

Our therapeutic efforts must be directed in a way to furnish aid to the entire organism in its struggle against disease, to strengthen its innate powers of resistance, and not merely to fortify one of the approaches, leaving the others unguarded. The indications of a rational treatment of disease are to combat the influences which have weakened the body and so have predisposed it to yield to the assaults of the morbific agents; to support and increase the cellular energies; to strengthen and stimulate the function of those organs whose office it is to preside over metabolism and furnish a suitable pabulum to the rest of the body; and to protect the sensitive nervous system, upon whose integrity so much depends, against injury.

The so-called causal treatment of disease is not always effective and its advantages are often illusory. In our well-meant efforts to repress and expel the causes of disease, we may easily go too far and injure the already weakened organism in its resistant powers. It will be of little avail to annihilate the greater part of the attacking force if we thereby so weaken the defence that it is unable to resist the small remnant of the enemy which has escaped the action of our destructive agents.

We must rather imitate nature in her therapeutic efforts, which, after all, are so often effective. The modern treatment of diphtheria by means of injections of a specially prepared antitoxic serum is an imitation of nature and is a brilliant exemplification, the orator maintained, of the wisdom of this course. The triumphs of orrhotherapy in the management of diphtheria have been great and indisputable.

In health as in disease all the organs work together, and it is in a disregard of this great truth that the chief danger of specialism exists. The specialist is too wont to consider the needs of one system or of one organ in a system, separating it from the body as a whole. This danger is an imminent one at the present day, and it is one against which the true scientific physician must never be weary of protesting. The therapist must be a man of broad views, and, however small and apparently circumscribed is the lesion he is called upon to treat, he must keep ever before him the sufferings of the entire organism, and must recognize and act upon the unquestionable fact that man is a unit and that we cannot hope to treat with success a part while ignoring the whole.

Finally, the speaker said, the nervous system must be strengthened and enabled to act its part in the struggle against disease. This most vital part of the human organism is not influenced by medication alone, but there is here room for that imponderable

therapeutic agent which is personal to each physician and which finds expression in his moral influence over the patient. To fulfil in the highest degree his divine mission the true therapeutist must be a physician of the mind as well as of the body, he must be able to inspire in his patient that confidence in himself and that hope in the efficacy of his remedies without which his best directed efforts will scarcely avail.

The second general session was then declared adjourned.

(To be Continued.)

THE NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, March 24, 1897.

WARREN COLEMAN, M.D., VICE-PRESIDENT, IN THE CHAIR.

DR. E. P. SHELBY, JR., presented a specimen of

Rupture of the Heart.—The lesion occurred in a woman, sixty-six years of age, who had been treated for heart disease ten years before. She was confined in an insane asylum for some time, but was discharged as harmless three years ago. During the past few months she had lived in constant fear of being poisoned, and had refused every article of diet except eggs. Three days before death she began to suffer from diarrhœa and nausea. These symptoms grew worse until the third day, when she died suddenly after a violent paroxysm of vomiting. An autopsy was held forty-eight hours after death, by Dr. E. J. Donlin, who had kindly sent him the specimen and the history of the case. The body was greatly emaciated. The brain was anæmic, but showed no other gross change. The left pleural cavity was filled with clotted blood. The right pleural cavity was normal. Both lungs were anæmic. There was a distinct tear in the left side of the pericardium, and the sac contained several ounces of blood. The heart was covered with blood, and on its posterior surface presented a rupture in the wall of the left ventricle, about one-half inch long, running parallel to and one-half inch from the ventricular septum, about midway between the apex and base. Around the point of rupture there was an extravasation of blood under the pericardium. On the inner surface of the ventricle was an L-shaped tear, whose long side ran from above downward, and measured one and one-half inches. The short side extended three-fourths of an inch to the left. The heart wall at the point of rupture was rather thin, and somewhat paler and softer than normal, but there was no indication of ulceration. Minute examination revealed a thrombus in the right coronary artery, which had started in a calcareous area about one inch from the aortic orifice. There were also two calcareous patches in the left coronary artery, which greatly diminished its lumen. As the thrombosed vessel was the one which nourished that part of the wall in which the rupture occurred, it was probably the predisposing cause. The heart weighed thirteen ounces. There was no valvular change except a slight thickening of the mitral valve. The stomach contained a small quantity of yellowish mucus and several pieces of hard-boiled egg. The mucous membrane was congested. The small intestine showed marked congestion in places. The kidneys, liver, and spleen were anæmic, but no pathological changes were noted. The violent effort at vomiting, which was probably due to the irritation of the hard-boiled eggs, seemed to have caused the rupture in the heart wall; and the fact that the pericardial sac was also ruptured would indicate that the heart had continued to contract after the initial rupture had occurred.

DR. WARREN COLEMAN said that it was the first case of rupture of the heart that had ever come within his observation, and it was exceedingly interesting from the fact that from the gross examination there was no evidence of any change in the heart at the location of the rupture. But in these cases of rupture of the heart there was almost always some lesion which appeared to have impaired the integrity of the wall.

Pertussis; Punctate Hemorrhages in the Brain.—DR. ROWLAND G. FREEMAN presented a brain which was the seat of punctate hemorrhages following whooping-cough. The specimen had been removed from a colored child, two and one-half years old, who had been admitted to the Foundling Hospital in a moribund condition. It had had, at the time, a temperature of 101.5° F. and a pulse of 180. There were general convulsions, with attacks of coughing, and these attacks were followed by some strabismus. The child died twenty-four hours after admission, and the autopsy was made forty-eight hours after death. There was no rigor mortis. There was one ounce of serum in the right pleural cavity together with a small amount of fibrinous exudate. The right lower and middle lobes of the lung, and the posterior fourth of the upper lobe, showed marked lobular pneumonia. In the left pleural cavity were four ounces of serum. The pericardium contained one ounce of serum. The right auricle was distended with a firm clot, which passed into the right ventricle and up into the pulmonary artery. The liver was considerably enlarged. The spleen was enlarged below the free border of the ribs. The stomach was distended with gas. The brain showed punctate hemorrhages throughout the cerebrum, but none in the cerebellum or in the pons. These hemorrhages were confined to the white matter.

The speaker said that in cases of pertussis, hemorrhages were common in many places, but were noticed most often, perhaps, in the conjunctiva. Epistaxis, hæmoptysis, hemorrhage from the ears, and purpuric eruptions were also not infrequent. Trousseau had reported a case in which a child was said to have cried "tears of blood." The occurrence of cerebral hemorrhage in connection with pertussis had been reported by Marshall, in 1885.

Dr. Freeman also presented specimens from two cases of

Large Waxy Liver in Children.—The first was that of a child of six years, who died at the Foundling Hospital, on March 21st. It had been under observation in the hospital for a number of years. In July, 1896, it was noted that the child had an upper lumbar and a lower dorsal kyphosis, with a sinus draining below the right hip. In September the child had gastro-enteritis, with a temperature of 103° F. In October an abscess developed in the lumbar region and the old sinus reopened. In November the liver was first noticed to be enlarged. There was no cough nor were there any signs in the chest. Examination on March 1, 1897, showed the liver to be very large and firm, and the spleen also increased in size. The urine contained twenty-five per cent. of albumin. On March 10th there was fluid in the abdomen, the extremities were swollen, there were signs of fluid in both sides of the chest, and the liver extended to the umbilicus. On March 21st the child died. The autopsy was made twelve hours after death. There was no rigor mortis. The body was very markedly emaciated. The peritoneal cavity contained twenty-five hundred cubic centimetres of clear serum. The lungs and large bronchi contained some mucus. The bronchial lymph nodes were enlarged, and one contained some fibrous tissue, looking somewhat like an old phthisical process; there was, however, no active tuberculosis found in these nodes. The diaphragm was at the fourth space on both sides. The liver extended from the fourth space to the level of the umbilicus; it was very hard and waxy. The spleen extended below the free border of the ribs and was also waxy.

The pancreas was large. The adrenals were enlarged, and apparently both were tuberculous. The kidneys were pale and waxy. The mesenteric lymph nodes were enlarged. There was a bone abscess connecting with the spine.

Dr. Freeman said that this was the first case of waxy liver that he had ever seen at the Foundling Hospital, an institution in which, for the most part, the children are under five years of age.

The second case of waxy liver occurred in a child of ten years. This child had had a persistent and progressive anæmia for very nearly a year. In September the hæmoglobin was only 27.5 per cent., but there was no leucocytosis. The cause of the trouble was not suspected. At the autopsy the examination of the lungs and heart was negative. The liver extended from the fourth space to the umbilicus, and was hard and waxy. The spleen extended to a line drawn from the umbilicus to the left anterior superior spine of the ilium. The left kidney was the seat of a very large abscess, and the capsule was hard and thick. The right kidney was pale and waxy. In this case the right adrenal, or the one on the side opposite to the kidney lesion, was tuberculous. There were also two tuberculous mesenteric lymph nodes. No other tuberculous lesions were found. The speaker remarked that, so far as he had been able to ascertain, tuberculosis of the adrenals is very rare in children. There was no pigmentation of the skin or other evidence of Addison's disease.

Dr. Coleman said that he had carefully examined the suprarenals in all autopsies that he had made during the past five years, yet he had found them infected in only three cases—all adults. From some experiments that he had made on animals he had been led to believe that there was something about the suprarenals that tended to protect them in large measure from infection.

Dr. Shelby asked if tubercle bacilli had been found in the pus from the abscess in the kidney.

Dr. Freeman replied that, owing to a misunderstanding, such an examination had not been made. The appearance was that of a tuberculous abscess, but microscopical examination of the wall did not give evidence of any tuberculous process.

Dr. David Bovaird said that the second child had come under his care first for a tuberculous process of the spine, and had been treated with a brace. After a year a psoas abscess developed, and after a while this ruptured. The discharge continued for some time, and then the sinus closed. Following that, a lumbar abscess appeared and steadily increased in size. The enlargement of the liver and spleen was apparently secondary to the lumbar abscess. It was interesting to note that, although the disease in the vertebral canal was apparently in process of healing, the lumbar abscess developed.

The society then adjourned.

Stated Meeting, April 14, 1897.

Warren Coleman, M.D., Vice-President, in the Chair.

Dr. John H. Larkin presented an

Aneurism of the Thoracic and Abdominal Aorta, which had been taken from a man, forty-five years of age, who had a pronounced syphilitic history. For a number of years a pulsating tumor had been noticed in the epigastric region, but it had never caused any distress. He entered the hospital about one year ago, and after remaining there for one and one-half months went out again. About two months ago he was readmitted for a severe pain in the back. It was found that the pulsation was much more marked than on his first entrance to the hospital; he suffered much from dyspnœa, and the heart was displaced laterally. The breath sounds were very indistinct in the left chest. One night while in the hospital he got up and walked across the ward, and then fell down dead. It was found that the aneurism had ruptured posterior to the peritoneum and had discharged downward toward the kidney. The case was interesting on account of the large size of the aneurism and the comparative absence of urgent symptoms. The seventh and eighth and ninth vertebræ were eroded.

Aneurism at Apex of Heart.—Dr. Larkin then presented a rather large heart, removed from a woman, eighty-six years of age. She had never complained of any cardiac trouble, and death resulted from apoplexy. The autopsy showed a small aneurism at the apex of the heart, with complete absence of cardiac muscle at the apex of the left ventricle. There was a replacement fibrosis at this point. Some parts were quite calcareous, and there was also slight interstitial myocarditis. The coronary artery was the seat of atheroma.

Aneurism of the Sinus of Valsalva.—Dr. Larkin presented still another heart. It had been taken from a man, thirty-five years of age, who died from chronic Bright's disease. There was a history of marked syphilitic disease. At the autopsy, in addition to marked chronic diffuse nephritis, there was a large aneurism of the sinus of Valsalva. The posterior coronary artery was found only with some difficulty, and it was markedly atheromatous. It could be traced up to the aneurism, but the opening into the aneurism could not be detected. The coronary artery contained a little semifluid blood.

Dr. Larkin said that Sibbs had made a collection of 860 cases of aneurism. Of this number 87 were at the sinus of Valsalva, 480 were of the whole arch, 140 of the ascending portion, 120 of the transverse portion of the arch, 112 of the ascending and transverse portions together, 72 of the descending portion, 20 of the transverse and descending portions of the arch. There were 71 aneurisms of the thoracic aorta, 131 of the abdominal aorta with the cœliac axis, and 26 of the lower portion of the abdominal aorta.

Dr. Shelby asked if in the case of aneurism of the sinus of Valvsalva, examination had been made of the muscular fibre; and, if so, if any fatty degeneration had been found in the region which should have been supplied by the coronary artery.

Dr. Larkin replied that the heart muscle was not fatty. If the coronary artery really had been occluded, there should have been an important lesion of the heart muscle itself. In this case there had been no symptoms at all referable to the heart.

Dr. Coleman said, regarding the question of the occlusion of the coronary artery, that in this connection the researches of Porter, of the Harvard Medical School, were of special interest. His experiments on the heart of the dog showed that the coronary arteries were terminal, and if one portion were occluded the part supplied by it became infarcted. Even though there were an anastomosis, there was no passage of blood from one coronary artery to the other by reason of the difference in pressure. If these experiments were correct, then we must assume that this coronary was open; otherwise there would have been a degeneration of at least a large part of the heart wall supplied by this artery.

Dr. Larkin said that a number of French pathologists had gone over this ground experimentally, and had come to practically the same conclusions. He now had in his possession a specimen from a case in which vegetations from the valve had gotten into the coronary artery and completely occluded it. In this heart there was a distinct softening of the heart muscle, and also a globular thrombus.

Peruvian Heads — Savage War Trophies.—Dr. Oscar A. Holder exhibited one of the Peruvian heads or trophies so highly prized by certain tribes near the head waters of the Amazon. He said that these tribes were almost constantly at warfare with one another, and instead of scalping a victim it was their custom to decapitate him and put the head through some secret process by which the features were wonderfully well preserved, appearing like a diminutive of the original. Fine metallic crystals could be discerned in some portions of the specimen.

Dr. Shelby said that he had just been speaking with a man who travels extensively in Brazil, and who had brought one of these heads to the Metropolitan Museum within the last few days. This gentleman had told him that the process consisted in skinning the head and packing the integumental covering with the bark of a certain tree. It was then hung up and smoked, after which it was dried in the sun.

Thrombosis of the Pulmonary Artery.—Dr. Warren Coleman presented a specimen of thrombosis of the pulmonary artery, removed from a woman, twenty-seven years of age, who about a month previous to her death had given birth to a child at full term in the emergency department of Bellevue Hospital. She was discharged at the usual time, the ninth day. About two weeks later she entered the general hospital with a moderate temperature, complaining of slight pain in the infra-axillary region on the right side. The presence of pus was suspected in the pleural cavity, since the uterus was free from sepsis. The patient was confined to bed. During the three or four days immediately preceding her death she suffered from slight shortness of breath, and the night nurse reported that after twelve o'clock on the night she died she had been very restless, tossing from one side of the bed to the other. A little before six o'clock that morning she had sat up in bed to bathe her face, and a few minutes later, while taking a cup of coffee, fell back upon the pillow. The house physician, Dr. R. E. Brown, was called, and he found the patient cyanotic and gasping for breath. The pulse was rapid, small, feeble, irregular, intermittent, and at last imperceptible. Stimulants were administered, but without avail, and the patient died in a few minutes.

The autopsy was not made until four days after death, but the body had been kept on ice and was in good condition. The pericardium, endocardium, and valves were normal. The right ventricle was markedly dilated and contained a large amount of dark, imperfectly coagulated blood. The walls of the heart were soft and light colored, presenting evidences of parenchymatous changes. The weight of the heart after the blood had been washed out was thirteen ounces. Part of this hypertrophy, at least, might be accounted for by the recent pregnancy. Both pleural cavities contained a moderate amount of liquid, though there was no pleurisy. The cut surfaces of the lungs were congested and œdematous. The lower first divisions of the pulmonary artery to both lower lobes contained thrombi which were intimately adherent to the walls of the vessels. This union did not extend entirely around the lumina of the vessels, and elsewhere the clots were simply in contact with the endothelium. When the thrombi were forcibly torn from their attachments, a rough, ragged surface was left, leading to the opinion that the arterial walls had suffered actual change at these points. This opinion was subsequently confirmed by microscopic examination. From the sections presented it was evident that the thrombi were at first parietal and partial, and that the vessels were subsequently occluded by further coagulation within their lumina. The arterial wall and clot merged into each other at the point of adherence, so that it was difficult to determine their respective limits. From the presence of cell elements, some of them fusiform, in the outer margin of the clot, it was believed that organization of this first-formed portion of the thrombus had begun. Evidences of infarctions were carefully sought for in both lungs, but without success. The pulmonary arteries beyond the thrombi were dissected as far as could be done with small scissors, without finding an embolus. The uterus was subinvoluted. The walls were thickened and the cavity was enlarged. The length of the uterus was sixteen centimetres; the breadth at the fundus was ten centimetres; the depth of the cavity from the internal os to the fundus was eight centimetres. The cavity of the uterus contained a small amount of dark brownish material, which did not appear or smell septic. The spleen was enlarged and dark. The kidneys were swollen, pale, and moderately congested. Sections showed moderate acute parenchymatous changes. Smear preparations of the clot contained numerous large bacilli, a few small bacilli, and a very few organisms apparently encapsulated and resembling the diplococcus lanceolatus. Cultures from the clot (unavoidably delayed for twenty-four hours) gave nothing but a large, rapidly spreading, foul-smelling, putrefactive bacillus. The incompleteness of the bacteriological examination was, of course, to be regretted.

Dr. Coleman said that the chief interest in this case centred around the etiology of the thrombosis. The occurrence of pulmonary thrombosis had been explained, he said, upon two theories—primary coagulation through changes in the constituents of the blood (Barker and Playfair), or as the result of embolism from the heart or a peripheral thrombus. There was no thrombosis of the iliac, femoral, or ovarian veins from which an embolus might have been dislodged, and the right heart contained only imperfectly coagulated blood, so that the dislodgement of an embolus large enough to have been arrested at the site of the thrombosis might be excluded. The theory of primary coagulation from changes in the constituents of the blood was scarcely tenable in the light of existing knowledge as to the causes of thrombosis. The changes which had been noted as present in the wall of the pulmonary artery rendered it probable that some injury was inflicted to the endothelial lining and that upon this site coagulation began. How this injury was inflicted would be merely a matter of speculation; he would suggest, however, that it was in some manner connected with a septic condition of the woman. In phlegmasia alba dolens coagulation sometimes takes place from causes within the vessel without a pre-existing phlebitis, and the inflammation afterward extends to the vessel wall and perivascular structures. From the researches of Prudden upon the localization of inflammatory processes after the intravenous inoculation of pyogenic organisms, it was known that such localization was determined by a lowering of local resistance, as by traumatism. That the traumatism might at times be slight, was shown by the occurrence of endocarditis during a septic puerperium, in which the only cause of injury which could be assumed was the normal closing of the valves or the impact of an embolus against them. In the present case, though no thrombus was found in the larger peripheral veins, it seemed not unlikely that an embolus was detached from a thrombus in a smaller vessel, which was not discovered, and, striking the wall of the pulmonary artery, determined the occurrence and location of the thrombosis. The shortness of breath which preceded death for several days might be explained by the gradual formation of the thrombus.

Dr. Larkin said that the shortness of breath for several days before death was an unusual symptom in these cases of pulmonary thrombosis, and would appear to indicate that the obstruction had formed slowly.

Dr. Coleman said that he believed the coagulation had first occurred at the side of the vessel, and that the lumen had been gradually encroached upon and finally completely occluded. In another case, in which death had occurred in five minutes, a large embolus had been dislodged from a thrombus in the right ventricle and had immediately closed one of the large branches of the pulmonary artery, causing almost instant death.

Dr. Larkin said that some months ago he had presented a specimen of thrombosis of the pulmonary artery. In this case a woman had done well for eight or ten days after confinement, and had then suddenly dropped dead. Here he had been unable to find any change in the endothelial lining which would account for the thrombosis. Unquestionably the specimen just exhibited under the microscope showed that the primary changes in this instance had occurred in the endothelium.

The society then adjourned.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

THE HOSPITAL FUNDS: THE AMERICAN, THE PRINCE'S, THE SUNDAY—THE SPECIAL HOSPITAL GRIEVANCE AS TO THE SUNDAY FUND—INCREASE OF DIPHTHERIA; HOSPITALS CROWDED—EXPERT ASSESSORS—A MUNIFICENT POOR-LAW SALARY.

London, August 13, 1897.

The American jubilee fund for endowing beds in our hospitals amounts to above £4,300. The surplus will be given to the Prince of Wales' fund. This latter it was yesterday announced amounts to over £180,000.

The Sunday fund this year reached £40,000, being less than last year by £2,124, but this deficiency is less than might have been expected considering the large amounts which have been collected for analogous purposes in celebration of the Queen's reign of sixty years. The distribution committee's report has passed the council and above £39,700 is in course of being distributed to one hundred and thirty-two hospitals and fifty-six dispensaries. Some £2,000 of this goes toward the purchase of surgical appliances in monthly proportions. Any further sums that may come in will be credited to next year's account.

The committee plumes itself on having received thirty deputations for conference or explanations, but this work is not so important as it seems to imagine; for nothing could surpass the partiality displayed at these conferences and the absurd adherence to certain fixed rules. As to the latter it is remarkable that St. Thomas' Hospital gets nothing because its accounts are not in the stereotyped form adopted by the committee. As to the former the chairman and others have always been hostile to special hospitals and sometimes discourteous to their representatives. Taking his cue from this, the secretary has "gone one better" and, as some one said, "made a hole in his manners." He told one person that his hospital had no right to exist—although it was older than the fund and had given up its separate collections for the general one, and therefore in common honesty was entitled to some share. He returned the accounts of a hospital duly audited by a chartered accountant on the system of the fund because the secretary had not added up for him the pages of contributions by subscribers. Many declare that there are only two courses for the special institutions to adopt. They must either unite and appeal to the public on the unfairness and prejudice, or else resume separate collections in the churches of their localities. Either course might do more harm to the general fund than good to the specialists—and it is to be hoped the managers of the fund will reform their proceedings and the secretary be told that his office does not give him liberty to pronounce in the name of the distribution committee his private and ill-informed opinions. *The Lancet* has done such splendid work for the fund and is so interested in it that little help can be expected from your contemporary in case of an appeal to the public against the committee; apart from that I should deprecate such an appeal even from the united special institutions, which, in spite of opposition, are still flourishing.

Although the general health of London has been very good of late, diphtheria has continued to spread and there is some difficulty in accounting for this disquieting fact. As I have reported, there will shortly be five hundred and forty-eight additional beds at the new Park Hospital, but in the mean time the pressure on the hospitals of the asylums board is so great that more beds have been crowded into the wards than were intended. This reduction of the air space calculated for the patients is recognized as an evil and to be tolerated only during a temporary emergency. Nor is overcrowding confined to the board's hospitals. The outbreak of beriberi in the Richmond Asylum, Dublin, has brought to the public's knowledge a condition of overcrowding there which has again and again been impressed on the authorities. A similar state has just been reported at Brookwood Asylum, where 1,085 to 1,190 patients occupy the accommodation provided for 1,050. The Surrey County Council seems to receive patients from the London Council, which is said to be in a still worse condition.

Mr. Justice Williams at a recent trial advocated the employment of medical experts as assessors, to be selected for their acquirements and not to be advocates for either plaintiffs or defendants. The plan has often been recommended by medical and scientific authorities, but hitherto our legal luminaries have been opposed to it. Now that a judge has spoken in its favor there is more hope of a reform.

The Hampstead board of guardians proposed to appoint a medical officer to the workhouse and infirmary at the princely salary of £40 per annum with rooms and rations. He was to have the double qualification, and in addition to his medical work was to do all the dispensing. The local government board has pronounced the salary inadequate and yesterday informed the local gentlemen that it must be at least £60, or if dispensing be included £80.

OUR BERLIN LETTER.

(From our Special Correspondent.)

MIDSUMMER DULNESS—THE TWELFTH INTERNATIONAL MEDICAL CONGRESS—ABSENCE OF UTERUS AND OVARIES—COITUS PER URETHRAM—CEREBRAL DISEASE IN THE NEW-BORN—LEUKÆMIC APOPLEXY—A TOOTH IN THE NASAL FOSSA—THE GONOCOCCUS TOXIN.

Berlin, August 15, 1897.

When at the end of July the university closes its doors and the professors with their families go off to the various resorts, then the medical societies also lapse into quiet, and their members have time to gain from their rest renewed strength for their labors in the autumn.

The coming events of the medical congress are casting their shadows before, even as far as Berlin. There will be a very large representation from this city, and as nearly all will start at the same time it is easy to

see that the railways, especially those in Russia, will be taxed to their utmost to provide transportation. It will evidently be impossible to provide for all without the putting on of extra trains, for, in addition to our own contingent, almost all the congress members from northern Europe and America will pass through Berlin *en route*. All the available sleeping-car accommodations have already been engaged, and the prospect for the majority is that they will be shipped to Moscow like a ton of herring, and arrive there half suffocated after a thirty-hour car ride. The Russian express trains creep along at a delightfully easy jog at just about half the speed of an ordinary accommodation train in America. We, of course, have reason to be grateful to the Russian government for the gift of free railway tickets; but the Russian is not so stupid or so generous as he might seem to be. In the first place the price of railroad transportation in Russia is very low, and in the next place the offer of anything free will attract a very much greater concourse and all of these "guests" will leave a goodly amount of gold in holy Russia. The Prussian railway officials are also wise in their own way. While almost all the other European railways and steamship companies have made very substantial reductions in the price of tickets to members of the congress, the Prussian minister of railways says simply: "*Non possumus;* the great congress is our sponge, let us squeeze it." In this action he is in direct opposition to his colleague, the minister of instruction, for in few countries is so much done for science as in Prussia with her numerous universities.

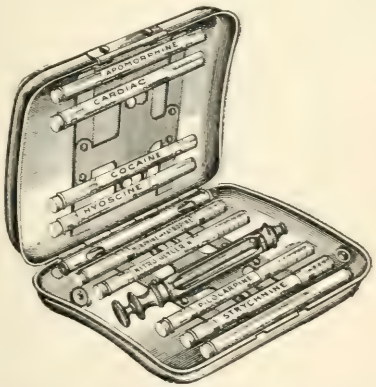
At the session of the Gesellschaft für Psychiatrie und Nervenkrankheiten held just before the vacation season, Dr. Grauck presented a patient in whom the vagina consisted of nothing but a shallow cul-de-sac, and no trace of uterus or ovaries could be discovered. The appearance of the patient was thoroughly feminine, but she had never menstruated. She suffered much from hysterical attacks, the first of which appeared soon after her marriage, and were perhaps excited by the attempts at coitus, which were always painful and the occasion of great excitement. The urethra was widely dilated and it was doubtless in this direction that penetration took place during the sexual act. At the same meeting Dr. Köppen read a paper on diseases of the brain in very young children. These affections have been hitherto but little studied; the brain has been examined macroscopically only, and in consequence of some superficial resemblances to that of an animal the various departures from the normal in conformation have been ascribed to atavism. In two cases examined carefully by the author, he was able to demonstrate that the changes were not at all due to an arrest of development, but rather to a true pathological process. Dr. Benda reported the case of a patient suffering from leukæmia who died with the symptoms of apoplexy. A careful examination of many sections of the central nervous system showed no lymphomatous disease anywhere except in the region where the apoplexy had taken place. One ought always to bear the possibility of such a complication in mind when in the presence of a sufferer from leukæmia.

At the last meeting of the Berlin Medical Society, Dr. Fränkel showed a patient having an inverted tooth in the left nasal fossa. The patient, a child, suffered from hereditary syphilis with resulting caries and necrosis of various portions of the nasal bones. During the attempt to extract the sequestra the operator came across a bony projection which it was impossible to remove, even with the saw. Closer examination showed that it was a tooth which apparently had been reversed, its crown projecting from the floor of the left nasal fossa. Dr. Wassermann then read a paper on the gonococcus toxin. He had made many experiments to discover a culture medium for gonococci which could be made use of in general practice. Up to the present time it had been possible to conduct culture experiments, which called for the use of sterile human serum-albumin, only in institutions where such a fluid could be readily obtained. The speaker had found that hog's serum was an efficient substitute for that of man, and he had succeeded in cultivating the gonococcus in a medium composed of hog's serum, casein-sodium phosphate, and peptone-bouillon. From such cultures he had been able to obtain a very potent toxin which caused fever and swelling of the glands, joints, and muscles. He had been unable to produce any immunity against the action of this toxin. These experiments offered a ready explanation of the occurrence of rheumatism after gonorrhœal infection. The gonococci die speedily indeed, in the inflammatory exudate, when deprived of oxygen, but this only the more readily sets free the inflammation-exciting poison, so that the destruction of the gonococci leads to no improvement in the disease, since there is no free discharge of the toxins. Dr. Wassermann advised, therefore, that all foci of inflammation due to the presence of the gonococcus-toxin should be opened up widely in order to give exit to it, for he maintained that there is no remedy which can oppose the action of this poison, and the only hope of relief is in getting rid of it.

New Instruments.

AN IMPROVED HYPODERMIC SYRINGE.

THE accompanying illustration shows the newest improvements in hypodermic syringes. This instrument is unique from the fact that it embodies very desirable features in both syringe and case. It is the outcome of many years of experience in this line of work. The case is made of aluminium and is curved to fit the body when carried in the vest pocket. It permits of



sterilization by boiling. The piston packing is made of improved vulcanized rubber. This is so disposed that by simply turning the piston head to the right the packing is adjusted at any point in the barrel. No lubricant is needed, the fluid to be injected furnishing all that is necessary. The packing does not shred, as is the case with asbestos, nor become hard and unyielding, as does leather. On the other hand, when it is found necessary to renew the packing it is not necessary to send the syringe to the manufacturer, since the physician can insert a new washer by following the written directions. The syringe was designed by the H. K. Mulford Company, of Philadelphia.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending August 21, 1897:

	Cases.	Deaths.
Tuberculosis	153	98
Typhoid fever	20	1
Scarlet fever	80	2
Cerebro-spinal meningitis	0	3
Measles	78	5
Diphtheria	138	10
Laryngeal diphtheria (croup)	4	0
Chicken-pox	2	0

Long Survival with Incised Wound of the Heart.—It is reported that a Hungarian, stabbed during a quarrel at Easton, Pa., on August 3d, survived for twenty-six hours an incised wound of the heart, found upon post-mortem examination to be three-eighths of an inch long.

A Novel Method of Arresting Hemorrhage in a Case of Hæmophilia.—Dr. Bienwald describes, in the *Semaine Médicale*, an ingenious method employed by him to control the bleeding from a small wound of the face in a case of hæmophilia in a child two years old. Having failed to arrest the hemorrhage by the application of ferric chloride, some blood was obtained by aspiration from a healthy subject and deposited upon the wound. In a few minutes coagulation took place and the hemorrhage at once ceased.

Becquerel Rays.—The rays of Becquerel, observed also independently by Prof. Silvanus Thompson, have been further experimented with, and the observations carried forward by Dr. Russell. It is found that not only uranium but many ordinary substances emit radiations, which although invisible to the human eye can penetrate opaque bodies. Such various substances as, *e.g.*, the section of a young larch tree, printers' ink, cardboard, lead, and tin, when placed for a certain length of time near a sensitive plate in a dark room, leave a distinct impression on the plate. It is stated, however, that while the radiations from the uranium compounds pass readily through glass, the latter completely stops the radiations from the substances in question. Whatever be the "mysterious force" emanating from such bodies, it is certain that increased temperature of the body which emits it greatly increases its activity, and also that aqueous vapor does not assist its action. According to Mr. Lewis Wright, Becquerel rays are "invisible light rays of an extremely ultraviolet character, *i.e.*, transverse vibrations in the ether, of extremely short period and wave length." And he continues: "It is now generally held that the Roentgen rays are ether waves of the same character, but still higher frequency; certainly not less and possibly much more than a hundred times that of green light. The absence of sensible refraction, polarization, and regular reflection is exactly what would then occur. The waves are probably simply too small to be reflected from any polish at present attainable, or polarized by any ordinary structure in a sensible degree.—*Treatment.*

A Moving Tale.—The Chicago mind is as fertile of imagination as Chicago water of typhoid bacilli. The *Inter Ocean* of that city recently described a wonderful invention, which it justly remarks cannot fail to be of great value in the study of diseases. "A micromotoscope has been invented which is a kinetoscope for photographing cell life in motion as seen in the microscopic field. The pictures are taken by the gelatin film at from five thousand to fifteen thousand magnifications, and at the rate of sixteen hundred to twenty-five hundred per minute. The images being magnified thousands of times when projected upon a screen, the views of some of the families of microbes are very realistic. It has been learned that some of them possess great intelligence. The photographs of blood in circulation in the thinnest part of the ears and webs of the fingers, showing its capillary or arterial motion and the changes going on in the white cells, are of great interest. They indicate something of the nature of life and disease. The stream of circulating human blood is so swift that the eye cannot keep pace with it, and the changes in the white blood cells are correspondingly rapid. Some of the pictures show a white cell on the fast-moving stream, like a white cap on the sea, constantly changing its shape. It throws out or takes in its arms like an octopus, seizing the microbes in its path. In disease this movement of the arms takes place with much less energy than in health." We have long believed in the superior intelligence of many of the schizomycetes, and we are glad to find our suspicions confirmed by the revelations of the micromotoscope.

A Quarantine against Consumption.—Californians are rebelling against the use of their State as a sanatorium for consumptives. There was a time when the salubrity of the climate and the consequent advantages to people of weak lungs were held out as an inducement to immigration. But too many have accepted the invitation, and there is a feeling now among the unafflicted that the incursion is dangerous to them. Just what they can do about the matter, however, is a puzzling question. Directors of the State board of trade have decided that some measures should be taken, and they have in mind a quarantine against the health seekers. Lawyers tell them that this may not be feasible, although no great difference would seem to exist between the right to isolate people ill with a contagious disease and the right to prevent the entrance of such people into the State.

Health Reports.—The following statistics concerning yellow fever, cholera, small-pox, and plague have been received in the office of the United States Marine Hospital service during the week ended August 21, 1897:

		Cases.	Deaths.
Small-Pox—United States.			
Birmingham, Ala.	May 16th to Aug. 14th	76	1
Montgomery, Ala.	August 7th to 14th	28	
Small-Pox—Foreign.			
Nagasaki, Japan	July 13th to 19th	10	2
Cardenas, Cuba	July 31st to August 7th	2	2
Singapore, India	June 1st to 30th	7	7
London, England	July 24th to August 7th	2	2
Glasgow, Scotland	July 24th to 31st	1	
Sagua la Grande, Cuba	July 24th to August 5th	5	10
Montreal, Canada	July 2d to 24th	14	5
Rotterdam, Holland	August 1st to 7th	1	
St. Petersburg, Russia	July 24th to July 31st	6	
Cholera.			
Bombay, India	July 13th to 20th	2	2
Singapore, India	June 1st to 30th	1	1
Kioto Fu, Japan	July 11th to 24th	1	1
Osaka Fu, Japan	July 11th to 24th	2	2
Tokio Fu, Japan	July 11th to 24th	5	5
Fukuioka Ken, Japan	July 11th to 24th	2	2
Kanagawa Ken, Japan	July 16th to 25th	4	2
Saitam Ken, Japan	July 11th to 24th	1	1
Calcutta, India	July 2d to 14th	3	3
Colombo, Ceylon	July 2d to 24th	5	5
Yellow Fever.			
Cienfuegas, Cuba	August 1st to 5th	1	1
Cardenas, Cuba	July 31st to 7th	2	2
Matanzas, Cuba	July 26th to August 4th	4	4

BRITISH MEDICAL ASSOCIATION—ADDRESS OF THE PRESIDENT.[1]

BY T. G. RODDICK, M.D., M.P.,

MONTREAL, CANADA.

You have been welcomed to the Dominion of Canada by the noble earl who is the worthy representative of our beloved Queen; you have been welcomed to the Province of Quebec, to which this city belongs, by our eloquent and justly esteemed lieutenant governor; the chief magistrate of our city has given you "*Cead mille failthe*" in a manner in which only an Irishman with such a great sympathetic heart as he possesses can give; and now I rise to welcome you on behalf of the medical profession in Canada, and to thank you for the honor conferred on this city and country by your presence here to-day. Would that I could find suitable language in which to thank you also for the high honor you have done me in electing me to preside at this great meeting of the British Medical Association, an honor which is appreciated none the less by the consciousness that it is not a personal matter but a compliment to Canadian medicine.

This meeting of the British Medical Association in Canada is an event which will serve still more to impress upon the memory of our people the year 1897, the year of the diamond jubilee of our beloved sovereign, Queen Victoria. In no part of her vast empire did her subjects celebrate the great event with more enthusiastic loyalty and devotion than in Canada, especially in this province, the home of the French-Canadians. We Canadians of both tongues love and honor our Queen. Long may she live! Deeply, too, have we appreciated here the splendid reception accorded in the old home to our premier, the Right Hon. Sir Wilfred Laurier, whose distinguished bearing and grace of manner eminently fitted him for the important part it was his peculiar privilege to play in the magnificent ceremonies of the jubilee. A French-Canadian, Sir Wilfred's presence in England as the chosen representative of the dominion was an object lesson to the empire and to the world in the harmony existing between the two nationalities which comprise the Canadian people.

And here let me express on behalf of every representative from the British Isles, and on behalf of every Canadian present, the genuine pleasure we feel in having among us on this memorable occasion so many of our brethren from the United States. This only proves the cosmopolitan character of our profession; this is only another recognition of the unity of medicine. Legislators may squabble, the air may be filled with wild alarms, and war may appear imminent day by day, but our relations are not disturbed in the slightest degree; our interests are common—we are kinsmen in science; we go forward hand-in-hand, irrespective of race or creed or color, having one intent only: the advancement of our noble profession, and through that the amelioration of the ills of mankind.

It is my privilege also to welcome the representative of another republic, La Belle France, to whose gifted men of science our profession is so greatly indebted. This gentleman, who bears the credentials of his government and officially represents the great nation of which he is so bright an ornament, is known far and wide as the professor of physiology in the University of France. Dr. Charles Richet. In coming to Canada it cannot be said, nor will he feel, that he comes to a foreign country, for in the Province of Quebec he will find another France, with a delightful mingling of the old and the new: his own beautiful language spoken with all the grace and purity of the old *régime*.

But we are further honored by the presence among us to-day of the most illustrious surgeon of our generation, Lord Lister, who stands for the rise and zenith of modern surgery. It has been well and truly said that as long as surgery is scientifically discussed Lord Lister's name cannot fail to be mentioned. We have only to compare the surgery of the time before 1873 with the surgery as practised to-day to appreciate all that he has done for the science. Can it be for a moment questioned that Lord Lister has made operative proceedings possible which only twenty-five years ago would have been considered criminal? Undoubtedly the most powerful agency in the development of surgery in this century has been the introduction of the antiseptic and aseptic methods of wound treatment which he initiated. It is due to his efforts that surgical wards have been freed from pyæmia, and the mortality of lying-in hospitals reduced to the limits of normal parturition. For the past twenty years honors many and great have been showered upon him. Oxford, Cambridge, Edinburgh, Glasgow, Dublin, Toronto, and now McGill, have vied with one another in hastening to do him homage. Our sovereign in conferring upon him the richly deserved distinctions which he bears with such gracious dignity only gives expression to the general feeling of his countrymen throughout the empire and his admirers the world over. We are glad, I say, to have him with us to-day: his presence is an intellectual stimulus and an energizing force in our deliberations.

It is, I understand, an unwritten law of the association that the president shall not in his address encroach upon the topics which belong by right and usage to the readers of the main addresses and to the presidents of the various sections. I have observed that the majority of my predecessors have contented themselves with discoursing on objects and circumstances of local interest: they describe the town or city in which the meeting is held, or perhaps they discuss questions of a public character. In the absence of an address on public medicine, others have taken that for their theme. It has been my unhappy lot to select and consider subjects only to find in quick succession that they had already been appropriated, either by the association *Journal*, in describing so fully Montreal and its surroundings, or by the editors of the official guide or souvenir, who have given a very

[1] Delivered at Montreal, August 31, 1897.

comprehensive description of Canada, or by some of the gentlemen who preside over the sections, who, I have been led to understand, purpose discussing questions of medical education. I fear therefore that what I have to say this afternoon will fall far short of the brilliant presidential addresses which members of this association have been accustomed to in other years. Indeed when I look at the long roll of eminent men who have been my predecessors in this high office—men oftentimes distinguished for their literary gifts as well as for their exalted position in the medical world—I confess that I marvel at my temerity in accepting so great a responsibility. In speaking of my predecessors allow me specially to refer to the retiring president, Dr. Henry Barnes, whose courteous and kindly manners, together with his sterling ability, makes us all glad to know that his election as a vice-president for life insures his continued official and active connection with the association. Here might I also be permitted to say how greatly I appreciated the many kindnesses and courtesies extended to me by the president (Dr. Saundby) and members of the council when in London last winter, making the initial arrangements for this meeting.

With respect to the other addresses which it is customary to deliver on these occasions, medicine will be dealt with by one whose reputation is now world-wide—by our Osler—whose professional education was in great part received in this city, and who, I am happy to say, is still a Canadian. How he has been able to escape the alien law is a puzzle to many; but he has really only been borrowed for a time; he is merely passing through the United States in bond. We are only waiting until we can find a place large enough to hold him, when we shall coax him back. Sorry am I that his old colleagues in his own department of medicine, Howard and Ross and Macdonnell, are not here to share with us the genuine pleasure we experience in finding him in the position which he occupies to-day. One of these, the late lamented Howard, had much to do with moulding his career and setting him to the task which he has so ably accomplished.

You will hear addresses in surgery and public medicine, delivered by gentlemen who have devoted their lives to their special subjects.

Before proceeding farther, however, allow me, for the benefit of those who may not be acquainted with the work of the British Medical Association, to give in as few words as possible a general idea of its organization.

The British Medical Association.—When, in 1832, Sir Charles Hastings, of Worcester, communicated to a few of his personal friends the idea he had conceived of a medical association which should bring the whole provincial profession of England into a common brotherhood, it may be safely affirmed that he did not dream that he was laying the foundation of an association which would ultimately not only embrace the whole of the British Isles, but extend to that Greater Britain beyond the seas, and become an association of imperial magnitude and of imperial importance and significance. I have no hesitation in expressing my belief that the British Medical Association will be an important factor in bringing to a successful issue that great scheme of imperial federation which now exercises the minds, and, let me add, the hearts, of the leading statesmen of the empire. Sir Charles Hastings' aim was to bring town into professional union with town, county with county; now it has become the aim of the society he called into being to add State to State and may I not say continent to continent?—until all the nations and peoples who live under the British flag are brought within the beneficent influence of the Association.

With respect to the objects of the association, as set forth on its foundation, they may briefly be stated to be:

1st. The collection of speculative and practical information through essays, hospital reports, infirmaries, dispensaries, or private practice.

2d. Increase of knowledge of the medical topography of England through statistical, meteorological, geological, and botanical inquiries; the investigation of the modification of endemic and epidemic diseases in different situations and at various periods, so as to trace, as far as the recent state of the art would permit, their connection with peculiarities of soil and climate or with the localities, habits, and occupations of the people.

4th. The advancement of medico-legal science through succinct reports of cases occurring in courts of judicature.

5th. The maintenance of the honor and respectability of the profession generally in the provinces by promoting friendly intercourse and free communication of its members, and by establishing among them the harmony and good feeling which ought ever to characterize a liberal profession.

During its earliest years the movements and proceedings of the association were quiet and unostentatious, the meetings simple in their arrangements; but it was not long before medical societies began to join the newer body, and towns in all parts of the kingdom soon came to regard it as an honor to entertain the association. Gradually the best men of each district enrolled their names, and the membership increased so greatly that subdivisions into branches became a necessity. Each branch, with its own ordinary and annual meetings, was practically a replica of the parent society, possessing its own president, vice-president, secretary, treasurer, council, and by-laws, subject to the approval of the council of the association, to which, besides, each branch sent representatives according to its numerical strength. In 1837, five years after the foundation of the association, there were three of these branches formed, namely, the East Anglian, the Bath and Bristol, and the Lancashire and Cheshire. By the end of 1878 the association had spread over the whole United Kingdom, the total number of branches at that date being thirty—one of the thirty, it is interesting to note, being Jamaica, the first colonial branch to be formed. It was organized in 1878. Two years later we find that Australia appears for the first time, contributing three branches to the association. Since then thirty-six more branches have been added, making a grand total of sixty-five, with a collective membership of nearly seventeen thousand. Of the branches twenty-seven are Indian and colonial. Doubtless before long those portions of Africa which are now becoming rapidly civilized will also add their quota, so that it is possible that within the lifetime of all present the British Medical Association will be represented wherever the British flag flies. As Nova Scotia is always to the fore in matters intellectual, it is not surprising that the first Canadian branch of the association should have been formed in Halifax. It was started in 1887, four years ahead of Montreal, Toronto, Manitoba, and British Columbia. Canada has now seven branches, the Ottawa and Quebec branches having been formed within the last year. The formation of the Manitoba, Toronto, and Montreal branches was the immediate result of the visit to this country of Mr. Ernest Hart. In 1891, Mr. Hart, who has been editor of the *British Medical Journal* since 1867, and who has been well and truly described as the pivot on which the machinery of the whole association revolves, passed through Canada in that year and addressed *en route* the members of the profession in

Winnipeg, Toronto, and Montreal. Of the Manitoba branch, which began with twenty-five members, Dr. Ferguson was nominated as president and Drs. Thornton and Lamont as vice-presidents. In Toronto the branch also began with twenty-five members, Dr. Macallum being nominated president and Dr. Thistle honorary secretary. In Montreal the meeting was largely representative in spite of the short notice given, and twenty-six members of the profession at once signed applications for membership. The officers nominated were: President, Dr. (now Sir William) Hingston; first vice-president, the late Dr. George Ross; second vice-president, Dr. James Perrigo. The members of the council were: Drs. Roddick, F. W. Campbell, and George Wilkins. In the course of a very happy speech made on this occasion by Mr. Hart he remarked that he looked forward to the time when the Canadian membership would be large enough to invite the association to hold a meeting in Canada; and he hoped that the first meeting held outside the limits of the British Isles might be held in this country. Little did we think at the time that Mr. Hart's hopes would be so quickly realized. But the idea has ever been present with us, and those who subsequently attended meetings of the British Medical Association in England have lost no opportunity of advocating the claims of Canada, and especially of this the metropolitan city of Canada, as a place of meeting for the association.

One of the secrets of success of the British Medical Association is that it makes no distinction in the treatment of its members. Colonial members have all the privileges of the British members, and are always warmly welcomed at the headquarters in the Strand and at the annual meetings. The association has a large reserve fund of £40,000 sterling, which is the joint property of the members, to be used for public and professional purposes, and any suitable applications for grants for medical research, whether from British or colonial members, always receive attention.

A gentleman to whom the association is greatly indebted is Mr. Francis Fowke, who was appointed secretary and general manager in 1872. At that time the association was in rather a precarious condition financially, owing to its deficient organization; but shortly after Mr. Fowke took up the reins of office matters were found steadily to improve. About the time he was appointed the subscriptions amounted to £4,677. Ten years later they had nearly doubled, the amount being £9,147; and in 1891 they had reached the very respectable sum of £14,759. It is interesting to note how closely the advertisements in the *Journal* kept pace with the increase in membership. In 1876 the amount received for advertisements was £1,992; in 1881, £6,089; and in 1891, £14,568. The head office, which had been in Birmingham, was moved to London in 1872, where, after two removals, the present commodious premises in the Strand were taken. In 1879 the association began the printing as well as the publishing of its *Journal*. The library, which now contains ten thousand volumes, and which includes nearly every modern medical work of note, and many valuable books of reference, has developed in that time. That the British Medical Association is the largest and most influential guild in the world cannot be questioned. Moreover, the good it accomplishes increases from year to year, and more than keeps pace with the expansion of the association. Imagine the mighty power of the collective action of seventeen thousand earnest men pitted against false dogmas and ever battling for the truth! It is not, however, by the greatness of numbers that the association will be judged—it is by the diversity and quality of results. It is impossible to imagine any combination of circumstances which would render this great association any less necessary or useful than it is to-day. It will undoubtedly continue to grow in numbers, to increase in importance, and to be ever more and more an influence making for the amelioration and elevation of mankind.

The Canadian people, and especially the citizens of Montreal, are highly flattered and gratified that Canada should be the first country without the United Kingdom to be honored by a meeting of the British Medical Association; and, while they hope that it will not be long before the honor is repeated, our people are not insensible to the claims of other portions of the empire, more especially the great island continent of the antipodes, Australia. Either Sydney or Melbourne would be a fit meeting-place for such an imperial organization as this, and should the next meeting which is held outside the British Isles be held under the Southern Cross our hospitable Australian kinsmen may count on a large contingent from the Dominion of Canada.

Climatic Conditions.—As it may be presumed that to the majority of those present here to-day Canada is almost an unknown country, I have thought that among one or two other subjects a few remarks on the atmospheric conditions and health resorts of the Dominion would not be without interest.

The best way to understand the atmospheric conditions of a country is first to understand its physical features. The physical features of Canada are very remarkable. Broadly speaking, the country is separable by climatic and physical conditions into three great regions, the eastern, central, and western regions, which approximately run north and south in the general trend of the continent. The eastern region, which includes the older provinces of the dominion—Ontario, Quebec, Nova Scotia, New Brunswick, and Prince Edward Island—besides the great fur territory stretching far to the east and northeast of James Bay, extends from the Atlantic to Lake Superior and the chain of great lakes running in a northerly direction from Lake Superior to the Arctic Ocean. Between this great chain of lakes and the eastern base of the Rocky Mountains is the immense interior continental plain which constitutes the central region of Canada, its southern part consisting of open prairie, its northern part of forest lands. The third part of the division, the western region, is naturally very well defined, consisting of the wide and wild mountainous border of the continent on the Pacific side—the Rocky, Selkirk, and Gold ranges, which form the great Cordilleran belt, whose average width in Canada is four hundred miles.

Eastern Canada, our first and largest region, is geologically of very ancient origin. Here geologists have placed the nucleus of the continent—the broad belt of crystalline rock of great antiquity called the Laurentian plateau. This region is remarkable for its immense number of lakes large and small, and for its irregular and winding rivers with numerous rapids and falls. Between the Laurentian plateau on the north and the Appalachian mountain system on the south, lies the great Valley of the River St. Lawrence. The basin of this majestic river covers 530,000 square miles, of which 460,000 are in Canada. Above the city of Quebec, the base of the Laurentian highlands and the ridges of the Appalachian system diverge, and the mighty river flows through an extensive low country of notable fertility, in earlier days the great granary of Canada.

It may be added, *en passant*, that Mount Royal, which gives such distinction and character to our city, represents the basal remnants of a volcanic vent of great antiquity. From its picturesque summit may be seen similar abrupt elevations far off toward the east and

south—Montarville, Belœil or St. Hilaire, Mt. Rougemont, with Mt. Yamaska behind it, Mt. Shefford, and the conical Mt. Johnson or Monnoir. The Adirondacks are visible in the distance to the southwest, and the Green Mountains to the southeast.

Included in the eastern region is one of the most remarkable geographical features of Canada—the great fresh-water lakes or inland seas, Superior, Huron, Erie, and Ontario, which form the perennial reservoirs of the St. Lawrence. Together with Lake Michigan, which is wholly in the United States, they have an aggregate area of 94,750 square miles, an area larger than that of Great Britain. They stand at four distinct levels above the sea—Ontario, 247 feet; Erie, 573; Huron, 581; and Superior, 602. The Niagara Falls, the greatest and most impressive of the natural wonders of our continent, are the direct result of the great height of Lake Erie above Lake Ontario, the river connecting the lakes being only a few miles long. Besides the St. Lawrence, eastern Canada has several other great rivers, notably the Ottawa, which has a course of 1,800 miles and a basin of nearly 1,000,000 square miles; the St. Maurice, the Saguenay, and the St. John, the glory of New Brunswick, which, together with the Atlantic slope, has a basin of 50,214 square miles. The central and western regions also have their abundant share of large and small lakes and great rivers, an account of which would fill reams of paper. It should be noted that the Canadian rivers and lakes collectively cover an area of 130,000 square miles, and contain one-half the fresh water on the globe.

I draw special attention to this series of vast lakes and rivers because it exerts an immense and beneficent influence on the climate of Canada. It preserves the mean temperature while the land experiences the extremes. In summer the water is cooler and in winter warmer than the land conditions, which tends to modify the differences and to favor uniformity of climate. Without these waters, too, we should have vast regions of comparatively little value, as in Africa, Asia, and in the United States west of the Mississippi River, where large tracts of land far from water are nothing more than arid wastes. Our climate is more uniform than that of Europe; the meterorological differences are produced by position alone, but Europe has a higher mean temperature, and the extremes there are not so marked or so wide apart as in Canada. Owing to the great area of Canada, extending over twenty degrees latitude, or from the latitude of Constantinople to that of North Cape in Norway, the range of temperature is naturally very wide. The southern boundary stretches over fully four thousand miles, along which line we find that southern Ontario has the latitude of Central Italy, Nova Scotia that of Northern Italy, Manitoba and Vancouver that of central Germany. Speaking generally, the Canadian summer may be stated at 60° F. to 70° F.

From its vast and varied extent, Canada may be said to be the possessor of several climates. Taking Solly's classification as to position, we have in Canada all the three land climates, the low, the medium, and the high. The first has an elevation up to 2,500 feet, the second up to 4,500, and the third from 4,500 upward. As to temperature and humidity, Canada comes under the category of "cold, moderate, and dry."

Health Resorts.—In the eastern region of the dominion there are at least two localities which have been proved to possess many of the qualities which constitute a climate for convalescents from fevers and other depressing diseases, and also for consumption in the incipient stage. I refer to the region in the Province of Quebec among the Laurentians north of this city, of which the village of Ste. Agathe is the centre, the other being the Muskoka district in Ontario.

The first has been called the Adirondacks of Canada, having many of the features, physical and climatic, of that now celebrated plateau situated in the northeastern part of New York State, and stretching from the Mohawk Valley in the south one hundred and fifty miles north, almost to the frontier line. The average elevation of the two regions is about the same, being from sixteen hundred to eighteen hundred feet. The immense pine forests, together with the moderate temperature, constitute the chief characteristics of the Canadian district, from the medical point of view. No very systematic meteorological observations have yet been taken of the Ste. Agathe region, but the indications will probably prove to be very similar to those of the American resort. It is in contemplation to erect a sanatorium on Trembling Mountain, overlooking the village of Ste. Agathe, which will doubtless in time rival the Adirondack Cottage Sanatorium near Saranac Lake Village, which has proved such a marked success under the able management of Dr. E. L. Trudeau. The elevation of the sanatorium will be twenty-five hundred feet, thus having an altitude of nearly seven hundred feet greater than the establishment at Saranac. It is the intention of the Quebec government to set apart a sufficient portion of the crown lands to form a natural park in that part of the province. It will be called the Trembling Mountain Park, and will cover an area of one hundred thousand acres of land, in which are several beautiful lakes. Within the boundaries of this park the sanatorium will be constructed. There is therefore no reason to doubt that we will shortly have within our own lines a health resort possessing all the advantages of the Adirondacks region, and capable of affecting for good the same class of patients now so decidedly benefited by a residence in those mountains.

One hundred miles north of Toronto, in the highlands of Ontario, is the Muskoka Lake region, an area of about ten thousand square miles, perhaps the most picturesque portion of the whole province. Within this district, which has a mean altitude above the sea of about eight hundred feet (two hundred feet above Lake Huron), there are nearly a thousand lakes and ponds, connected by innumerable streams. The chief lakes are Muskoka, Rosseau, and Joseph. These contain about four hundred islands. It is a region abounding in pine forests; the climate is dry, and the air pure and invigorating. The Muskoka region has been found undoubtedly to possess remarkable climatic advantages for those with phthisical tendencies. The death rate from phthisis in this section of Ontario is proved to be less than one-tenth the rate which obtains in other parts of the province. At Gravenhurst the Muskoka Cottage Sanatorium for the cure of incipient phthisis has recently been founded, under the best auspices, with accommodation for forty patients. The present sanatorium consists of a large and well-planned main building, surrounded within easy distance by a number of small cottages. The grounds, which embrace seventy-five acres, are situated on Lake Muskoka. Pine forests and rocky ridges protect the buildings on the north and west sides, whence come the colder winds in winter. Like the Adirondacks sanatorium, the intention is to occupy it all the year round. The progress of this institution, at present in the experimental stage, will be watched with much interest.

In the central region of Canada, that section of the Northwest Territories known as southern Alberta—the home of the cowboy—has much to recommend it as a health resort. This strip of prairie and hill

country is bounded on the north by the Canadian Pacific Railway, and on the south by the international boundary line; its eastern boundary extends as far as Medicine Hat; its western boundary to the summit line of the Rockies and British Columbia, comprising in all an area of about twenty thousand square miles. The plain here has an elevation above sea level of twenty-seven hundred feet, which gradually increases up to the entrance of the Crow's Nest Pass, where the elevation is forty-five hundred feet. Calgary, the capital of Alberta, is itself thirty-five hundred feet above sea level. With this gradual incline from a low to a high level altitude the patient can choose the locality which suits his particular case. In a long experience Kennedy knew of only two cases of phthisis originating in that country—one of acute tuberculosis with a strong hereditary taint, which proved fatal; the other, of the ordinary type, recovered without leaving the place. He claims for the climate of southern Alberta a dry aseptic atmosphere and a dry soil, the greatest possible number of sunshiny days (ninety per cent.), with cool nights. Patients can live there all the year round, and with the exception of an occasional snowstorm, which may cover the prairie to a varying depth, nothing need interfere with their practically living in the saddle. The so-called chinook wind has a remarkable influence over all this western section of Canada. It is a warm wind which blows with varying intensity from west to southwest. McCaul, who describes it very graphically, speaks of its approach being heralded by the massing of dark clouds above the mountain tops, and a distinct wailing and rumbling from the passes and gorges. Its effect in winter is little short of miraculous. When the real chinook blows the temperature often rises in a few hours from 20° below to 40° above zero. The snow, which in the morning may have been a foot deep, disappears, and before night everything is dripping. But in the space of a single day all the water is lapped up by the thirsty wind, and the prairie is so dry that a horse's hoof hardly makes an impression.

The cases which have been most especially benefited by Alberta's climate are pulmonary tuberculosis in the earliest stage, although neurasthenics and anæmic women are likewise favorably affected to a marked degree. It is well known that delicate lads sent from the British Isles to this section of the Northwest to work on the cattle ranches become in a year or two healthy and vigorous men, and are scarcely recognized on their return.

Still farther west, and nearly midway between Calgary and the Pacific coast, is the beautiful Valley of Kamloops, another all-the-year-round resort which has much to commend it to those suffering from many forms of tuberculous disease. This picturesque valley, which lies between the Rocky Mountains and the Cascade Range, has a low altitude climate of eleven hundred feet, but is exceedingly dry, showing an annual rainfall of only 11.05 inches, with an average of about seventy-five rainy days in the year. The rain soon disappears, the soil being light and gravelly. In this region we have an illustration of the local variability of climate recently pointed out by Bryce, who, in referring to the two not very distant localities of Vancouver and Kamloops, showed that, whereas the former has an annual rainfall of thirty-five inches, the latter records but eleven inches and a decimal. The mean annual temperature of the Valley of Kamloops is 46.03 F., the annual range being only 22.8°. The tuberculous patients who appear to be most benefited by a residence in Kamloops are those in whom there is a tendency to chronic congestion. Cases of bronchitis are likewise said to do well there. The climate can also be recommended for consumptives in whom cardiac disease exists as a complication. That Canada is an exceptionally healthful country is the general testimony of the army and navy surgeons who have been stationed in Canada with the different regiments from the time of the conquest to the present day. Crawford, who was attached to one of the regiments stationed in Montreal many years ago, and who subsequently left the army and practised in this city, published elaborate and carefully collected statistics to prove that few portions of the British Empire have a climate equal to that of Canada. In fact his statistics prove conclusively that, out of every one thousand of the troops stationed at the various garrisons throughout the empire, the percentage constantly ineffective from sickness was smaller in this country by seven per cent. than at Gibraltar, which was then taken as the type. I think it can be satisfactorily proved that Canada is expressly fitted to develop a hardy race capable of great endurance. The races of the British Isles and the French race have certainly not degenerated here. Hingston proved this very conclusively some years ago by observations made upon the medical students attending the various schools in this city. He found that the lumbar strength of the British Canadian of the third generation exceeded by twenty pounds that of the recently arrived English and Scotch students. But the French Canadian of the tenth generation did better than all by nearly thirty pounds. Not only has the French Canadian increased in strength but also in height and weight over the original Normandy stock.

Has the intellectual improvement in our people kept pace with the physical? We are a modest people, but I think we can say with truth it has. We have a very respectable literature of our own, but the best intellect of the country is as yet absorbed in the practical affairs of life, and has too seldom found expression in art and literature. It is not very long since a distinguished American litterateur, Charles Dudley Warner, gravely attributed what he called the literary inactivity of Canada to the coldness of the climate. He said, in short, that the cold benumbed our intellectual faculties, and we had to spend so much of our energy in trying to keep warm that none was left for any other purpose. It must be admitted that if we measure the intellectual capacity of our people by the number of books produced in Canada the result is not all we might desire; but the climate is not to blame. Especially is it not the cold, for the winter is the season devoted pre-eminently to intellectual effort and intellectual amusements. If Mr. Warner had said that the heat of our summer was an unfavorable factor in our intellectual life he would not have shot quite so wide of the mark; he would not have been right, but he would not have been quite so wrong. The very vicissitudes of our climate, by training the system to endure severe physical conditions, must react favorably upon the mental attitude.

Canadian Spas.—We have in Canada several mineral springs of undoubted therapeutic value, and they are pretty generally distributed all over the dominion, although differing materially in temperature and composition. The best known Canadian spas are the Caledonia, the St. Leon, and the Plantagenet Springs, in the Province of Quebec, and the Banff Springs in Alberta. Other springs in the Province of Quebec are the Abenakis and the Caxton. Besides these there are at least three or four artesian wells or springs. Of these the chief are the Laurentian Spring, in the east end of this city (a mild alkaline water with sodium bicarbonate as its predominating ingredient), and the Radnor, a well of some considerable repute situated in the county of Champlain. This was discovered a very few years ago when boring for water to supply the workpeople engaged at the well-known Radnor Forges. The well is over four hundred feet in depth. In the Prov-

ince of Ontario the chief springs are the Winchester and the Preston, and those in the town of St. Catharines, near Niagara Falls. The best known and the most popular are the Caledonia Springs, situated on the line of the Canadian Pacific Railway about midway between Montreal and Ottawa, and about nine miles from the Ottawa River. They consist of four springs—the gas, the saline, the white sulphur, and the intermitting or Duncan spring. The first three are situated within a distance of three or four rods of each other, and the mouths of the latter two are not more than four feet apart. The intermitting spring is situated about two miles from the others. This is so named because the discharge of gas is not regular, some minutes elapsing between the periods of quiescence and disturbance. The average temperature of these springs is about 46° F. The intermitting spring has the largest percentage of chloride of sodium, and differs from all the others in possessing a greater portion of chlorides of calcium and magnesium. It has also nearly twice the proportion of carbonate of magnesium that the others contain. It has been found that taken judiciously and under advice these waters have a remarkable effect in subacute and chronic rheumatic conditions. People suffering thus are found flocking to Caledonia from all parts of this continent and even South America, especially during the months of July and August. Gouty conditions depending upon liver disturbances also yield very readily to these waters. The waters of St. Leon and Plantagenet are similar in many respects to those just described, and as a rule suit the same class of patients.

All the springs so far mentioned yield cold waters, but Canada also possesses the most famous thermal springs on this continent.

Banff, now a picturesque town magnificently situated in the heart of the Rocky Mountains, yet within the limits of that division of the Northwest Territories known as Alberta, has become one of our noted health resorts, although frequented more on account of its remarkable thermal springs than for its climatic advantages. The town is built on the banks of the Bow and Spray rivers, two large glacier streams, and is surrounded by mountains towering many thousands of feet above the level of the sea. The winter is short, beginning in December and ending in February, and is much milder than in Ontario. Very little rain falls, and the days as a rule are bright and cloudless. Prolonged periods of warm weather are experienced during winter. March and April are variable: May is warm and bright; June is the month in which the greatest rainfall occurs; July, August, September, and October are very warm and very dry, with cold nights. At all seasons with the exceptions perhaps of June the air is dry and notably aseptic. It is positively stated that no case of malaria or tuberculosis has ever been known to originate at Banff. Independently of the springs, then, Banff has much to recommend it from a climatological standpoint.

The far-famed Thermal Springs of Banff were discovered some fifteen years ago during the construction of the Canadian Pacific Railway. At its source in the mountain side it has a temperature of 127° F. and the air is charged for some distance around with the steam emitted from the pool to which the water flows. The most recent analysis shows it to contain the following ingredients:

Calcium sulphate	[illegible]
Magnesium sulphate	[illegible]
Calcium carbonate	3.29
Sodium sulphate	[illegible]
Sodium carbonate	[illegible]
Silica	traces.
Organic matter	traces.

The waters of Banff have been used with great benefit in rheumatism, gout, sciatica, and glandular affections, in certain forms of skin disease, and especially, it is thought, in tuberculous affections of the skin and mucous membrane. Aided by the admirable climatic conditions the waters have also been found to benefit in a marked manner functional diseases of the liver, stomach, and kidneys, and tuberculous joint affections. In debilitated constitutions from any cause the activity of the skin is noticed to be increased, the heart and vascular system are strengthened, and the muscular and nervous systems much improved in tone. Rachitic and delicate children are much benefited by the Thermal Springs. This seems a larger order; but the therapeutic effects of these springs have been carefully studied by competent medical men who have been stationed there for some years. The climate doubtless assists materially the action of the waters in very many cases.

I doubt if the Canadian profession sets a sufficiently high value on the therapeutic properties of our own mineral springs. When visiting the Spas of Great Britain and Europe, one is impressed by the caution exercised by patients in the method of using the waters which have been prescribed. There, competent local medical men are always to be found who can give the proper advice regarding the water to be taken for the ailment from which the patient suffers and the judicious use of baths. Here, unfortunately, in many places no professional advice is available, and the patient consequently does very much as he pleases, or as the hotel proprietor may advise, and in consequence more harm than good constantly follows the use of the waters.

Medical Education in Canada.—The general question of medical education is one of great importance and of unceasing interest, nor is this interest confined to the profession: it is becoming universal. The needs of medical education are fortunately being more fully realized by those who on accouunt of their wealth and influence are in a position to render that substantial assistance which is so requisite. The time was when every medical school was a purely proprietary concern "run" for the money that was in it. We feel in Canada, and I think I can speak for the profession in the neighboring republic, that this day is passed, that high-minded philanthropists like the Right Hon. Lord Strathcona and Mount Royal, the late John Henry Molson, the McDonalds, the Drakes, and others with us, and the Johns Hopkins, the Stanfords, the Vanderbilts, the Rockefellers, the Miss Garretts, and others with them are beginning to realize that unendowed instruction in medicine must lead to imperfect results, and that private endowment, in the absence of State aid, has become an absolute necessity to a proper medical training. I am not an advocate for State aid to universities, and I rejoice that the university to which I have the honor to belong is not so dependent, as it might thus be deprived of those gifts of private munificence to which I have just referred. All honor to those far-seeing, open-handed men and women who are giving of their abundance in order to elevate the standard of medical education and by so doing benefit their kind. As Gould very tersely puts it in one of his clever articles: "I think our reliance must be upon private bequests, and these can be secured only as we interest the rich. We must never weary in showing the neglect of the greatest, most palpable, most certain means of doing good. There is a strange fatality in men, an unaccountable inability of seeing the need that lies nearest the good that is dearest. There is more money to-day devoted to astronomy than to the prevention of disease. It is positively wonderful to think that men should be more interested in stars and constellations than in their bodies and their physiological life."

A question which is nowadays agitating the minds of those especially interested in medical education is the kind of groundwork which is likely to bear the most direct relation to the future studies of the medical student. I think it is now conceded by all that he is placed at a greater advantage who first passes through an arts or a science course. I am happy to be able to report that from fifteen to twenty per cent. of those who are studying medicine in this country today have had a collegiate training in either arts or science. Which of the two should the parent or guardian choose? Had I a son whose instincts were in the direction of medicine I think I should choose for him the science course. The late Professor Huxley thought it was a most self-evident proposition that the educational training for persons who proposed to enter the medical profession should be largely scientific; not merely or even principally because an acquaintance with the elements of physical and biological science is absolutely essential to the comprehension of human physiology and pathology; but still more because of the value of the discipline afforded by practical work in these departments in the process of observation and experiment, in inductive reasoning and in manipulation.

The subjects in the science curriculum might be specially selected for the future medical student. Of course it may be said in favor of the arts course that many of the subjects, such as physics and chemistry, constitute part of the curriculum; but then calculate the loss to the future surgeon of that training of the hand and eye which would lead him up to be a skilled operator; or to the scientific physician whose complicated instruments of precision employed in the diagnosis of disease need some mechanical knowledge for both their use and repair—besides the number of those has been increasing in number and complexity with the increase of scientific knowledge.

But can we not make a new departure, can we not urge that a special scientific education be arranged by the universities for those who desire to enter the medical profession? Such a course would embrace elementary Latin and Greek, French and German, physics, chemistry, biology, psychology, elementary mechanics, a practical laboratory course on electricity and drawing. After two years' study this might entitle the successful candidate to the degree of licentiate in science.

Something of this kind has been recently attempted in the University of McGill. By a special arrangement with the faculty of arts it is now possible for students to obtain the degree of B.A. along with M.D., C.M., after only six years of study. It has been decided to allow the primary subjects (anatomy, physiology, and chemistry) in medicine to count as subjects of the third and fourth years in arts. It follows, then, that at the end of four years' study a student may obtain his B.A. degree and have two years of his medical course completed. The last two years of study are of course devoted to the third and fourth year subjects in medicine. A certificate of licentiate in arts will be given along with the professional degree in medicine to those who previous to entrance upon their professional studies proper have completed two years in the faculty of arts, and have fully passed the prescribed examinations therein. By this plan also during the first two years of the arts course the medical student practically completes his studies in physics, chemistry, botany, and elementary psychology. This scheme is still in the experimental stage, but there is every reason to believe that it will result satisfactorily. What deters so many from taking a full course in arts or science before entering medicine is the length of time consumed before the doctorate degree is reached, although I hope the time is not far distant when every graduate in medicine in Canada shall of necessity be also a graduate in arts or science. I might state that the standard for the ordinary matriculation examination for entrance to medicine exacted by all universities and licensing boards in this country is, with one or two exceptions, very high. I doubt if the requirements in this way of the Medical Council of Great Britain are any higher.

Now as to the purely professional portion of medicine, I might state that we have in the Dominion of Canada no fewer than eleven medical schools, including one for women only, all having the power of granting degrees and all connected directly or by affiliation with university bodies. To enumerate them: Beginning with the Atlantic provinces, we have in Halifax the medical school attached to Dalhousie University, the only medical school in the Maritime Provinces; in this province there are four schools, Laval in Quebec, Laval in Montreal, McGill and Bishop's in Montreal; in Ontario, four schools, namely, the Royal College of Physicians and Surgeons, Kingston; the University of Toronto Medical Faculty, Trinity Medical College, and the Ontario Women's Medical College, in Toronto; in London, Ontario, the Western University Medical Faculty; and lastly, in Winnipeg, the Manitoba University Faculty of Medicine. All told, we had in Canada, during the last winter session, two hundred and eighty-six teachers, including professors, lecturers, and demonstrators, and seventeen hundred and thirty-six students. The tendency for the past two years has been to increase the teaching staff quite out of proportion to the increased number of students. Taking McGill, we find that there are in the present year fifty-three teachers for three hundred and eighty-eight students, being a proportion of nearly one to eight. Laval, in Montreal, has thirty-six teachers and one hundred and ninety-seven students, a still greater proportion. The Toronto School of Medicine had during the past year forty-one teachers and two hundred and ninety-three students. We find that this proportion compares well with the larger schools in the United States; thus, in 1893, there were in Harvard Medical School seventy-one teachers to look after four hundred and seventy-one students; at the Columbia Medical College in New York with six hundred and sixty-one students there were one hundred and five teachers (one to six); in the University of Pennsylvania the teaching staff in the same year comprised only eighty-four members with eight hundred and twenty-five students, being a little over one to ten. What does this mean? Ten years ago, when McGill had two hundred and thirty-seven students, a staff of twenty-three professors and demonstrators was considered sufficient. Why are so many more thought necessary nowadays? The number of subjects taught has not increased very much. The answer is that the subjects are differently taught; the old-fashioned daily didactic lectures are now given two or three times a week only; although I should be sorry to see them further reduced in number, I believe that so many are absolutely necessary. It is in the dissecting-room, the chemical, physiological, therapeutical, and pathological laboratories, that we see the change. These which before were for the most part only "side shows" are now made to hum with the practical work which is done within them, while demonstrators are moving about busily engaged in examining and instructing.

In clinical teaching also we have made marked advances. A creation of the last few years is the clinical demonstrator, who takes small classes of students into the wards or the out-door departments of our hospitals and gives them that "bedside instruction" which is so essential, leaving the clinical professor to deal with the full classes in the lecture or operating

room. Thus each student is enabled personally to examine the case, to study the physiognomy of disease, and to make deliberate, thorough, and systematic examinations. He thus learns to use his special senses and gets into careful habits of observation, which, once thoroughly acquired, will be found to contribute largely to future success. With this in view we encourage students to attend the out-patient department of the hospitals as early as the second year.

In order to make the clinical instruction more complete and more thorough, chemical and bacteriological laboratories have been added to the pathological departments of our hospitals. Thus it will be seen that laboratory methods everywhere prevail, all with the idea of developing the scientific spirit in students and of cultivating methods of thought with observation.

The question sometimes arises, however: May the student not be getting too much of a good thing? Is it not possible that laboratory teaching may be overdone?—because, as Welsh very truly says: "The student whose knowledge of a subject is derived exclusively from laboratory courses is likely to lose his perspective in details, to acquire only a fragmentary knowledge of the subject, to fail to comprehend the general bearing of observed facts; and not to acquire the general principles and systematic conceptions which are essential. Laboratory work should be accompanied and supplemented by the reading of textbooks and by lectures." I am convinced that with us in Canada laboratory work is not overdone, but, on the contrary, in some departments needs and deserves further encouragement. I hope every laboratory teacher in the country realizes that the object of a college is to give a good general education, and not to make experts in various branches. I have long felt myself, however, that the didactic lectures were being unfairly dealt with. There is a feeling abroad that they should be practically elbowed out of sight. I think the didactic lecture has its place in the medical course; and while I quite feel that the old plan of compelling students to listen to five didactic lectures a week in all of the great subjects was a mistake, I still feel that a good lecturer can teach in this way a certain something which cannot be imparted by practical instruction or by recitations. The personal influence of a good lecturer very often makes an impression which nothing else can make; and if such lectures are made also demonstrative, as by the use of diagrams, the lantern, experiments, etc., they must of necessity fill a very important place in the medical course.

Hygiene is at last receiving in this country the attention which its importance demands: all medical schools in Canada have facilities for teaching it. In McGill University the scope of the teaching of hygiene has been vastly extended, thanks to the generous endowment of that department recently by the chancellor, the Right Hon. Lord Strathcona and Mount Royal. The subject can now be taught in a scientific and, at the same time, eminently practical manner. There will be three teachers associated with the professor himself, viz., the heads of the departments of practical chemistry, of pathology, and of bacteriology.

This is following very much the German system, also adopted by the University of Pennsylvania, the chemical and bacteriological aspects of the subject being regarded as really the most important. An extensive working museum, with sanitary apparatus of every kind, forms part of the scheme, and will doubtless add greatly to the efficiency of the course when it is completed. Should the experiment succeed you will be rejoiced to hear at no distant date that the other schools in Canada have followed the lead of their elder sister.

I fear I have given you a very imperfect idea of medical education in Canada; and it may be charged against me that I have been partial in my description to my own university; but I assure you that such was farthest from my thoughts. The medical faculty of McGill University has the right of seniority and might fairly, I think, be taken as a type of Canadian medical schools. Be assured there is no mean spirit of rivalry abroad. We are all working with one object only, the advancement of medicine in Canada. The teaching facilities of some medical schools in this country may be, and are actually greater than others, owing to the munificence of citizens, and the school attached to McGill is, I am happy to say, in that position; but, although assistance has been rendered in a general way, with two exceptions the chairs are still unendowed. Yet we have great expectations which we hope will be realized in the near future. Let us hope that our sister universities throughout Canada will be equally fortunate; so that before long we shall be able to report that we are all marching abreast equally equipped.

The facilities for clinical teaching in the larger cities of Canada are admirable. Speaking for the city of Montreal, we have in the five general hospitals, the Hôtel Dieu, Montreal General, Notre Dame, Royal Victoria, and Western Hospitals nearly eight hundred beds. The number of students attending the three medical schools was, last session, six hundred and forty-six; and considering that only about half—those of the third and fourth years—have access to the wards, there will be at least two beds for each student. The number of outdoor patients attending the five hospitals daily would aggregate at least three hundred, so that there could be no possible cause for complaint regarding both the quantity and quality of clinical material available in this city.

While on the subject of hospitals, I would take this opportunity of saying that the training-schools attached to the larger English hospitals are in a very flourishing condition and are found to contribute not a little toward the thoroughness of the practical teaching. It was my intention to have referred at some length to the whole question of nurses and nursing, but the limits of this address forbid. I might say, however, while as a profession we feel the absolute necessity for the training-school, and thoroughly appreciate the services of the well-trained nurse, both in hospital and in private practice, there is the fear that the supply may soon exceed the demand. A project is on foot now, however, which may delay, if not actually prevent, such a result. I refer to the recent establishment by that most estimable and charitable woman, the Countess of Aberdeen, of the Victorian Order of Nurses—another outcome of the jubilee of our beloved Queen. Her Excellency's idea in establishing this order is to supply the sparsely settled parts of our great Northwest, the outlying districts of Canada generally, and the poor in towns and cities with nursing aid. In this great work hundreds of nurses will in time be employed. The scheme, which is purely non-sectarian, and appeals to all, irrespective of nationality, when thoroughly worked out and more generally understood will become one of our national institutions. Let us wish it every success.

Medical Legislation in Canada.—Time will not permit of my discussing the subject of medical legislation in Canada at any length; and besides you will find it very fully treated in the excellent official guide or souvenir, prepared for you by the executive committee. In addition I might explain, however, that when the British American provinces became confederated in 1867, under the British North America act, the governance of educational matters was taken away from the federal authorities and handed over to the provinces, each to look after them in its own way. In con-

sequence we have since had a curious complexity of medical legislation, there being practically no uniformity among the provinces in regard to standard of study or qualification for practice. Each province has its own medical board or medical council, as the case may be, which has the power to grant license to practise either after examination or on simply presenting the diploma of certain recognized universities. In the provinces of Ontario and British Columbia an examination is exacted; in the others the license is given under certain restrictions on presentation of the degree, although in the Maritime Provinces an examining-board is now about to be established. In this way, as can readily be seen, a Chinese wall is built round each province, and the frontier is carefully guarded, so that it is unsafe for a medical man to pass from one to the other unarmed with a license, because of the risk of fine or even imprisonment. Such a condition of affairs is hardly credible and probably exists nowhere else to the same extent. What is the remedy? Two remedies have been suggested—either the establishment of a central examining-board in each province, with a uniform standard of matriculation and a uniformly high standard of curriculum, which shall in time lead up to a general scheme of reciprocity; or, secondly, a dominion examining-board. The first scheme is at present under serious consideration, although there are many difficulties in the way of its accomplishment, none of which is insuperable, however, providing a spirit of conciliation prevails. The second alternative (a dominion examining-board) would in many respects be more desirable, because not only could the licentiate practise in any part of the dominion, but he could register in Great Britain, and thus receive recognition all over the empire. As you are doubtless aware, we, as a profession, suffer in this country from being inhabitants of provinces which are confederated. In an enactment, now of some twelve years' standing, the British Medical Council decided, in effect, to recognize the degrees of universities situated in autonomous provinces only. As a consequence, Australians obtain privileges which are denied to us, they being permitted to register in Great Britain without examination. We are being punished for belonging to a colony whose form of government is recognized to be in advance of theirs and likely to be imitated by them. Let me give our Australian brethren a hint: if the confederation of your provinces be in contemplation, see to it that all matters of professional education are left in the hands of the central government, at least as far as qualification for registration is concerned. By so doing you will avoid the almost inextricable tangle in which we in Canada find ourselves. Let common-school education go to the various provinces if you will, but for the profession of medicine (and doubtless law also) there should be a uniform standard of matriculation, a uniform curriculum of medical studies, and one central examining and registering board, composed of the best men from all the universities. We hope in Canada to reach that ideal at no distant date; in fact I have the very best authority for stating that it is not impossible of accomplishment. Some scheme of reciprocity first arranged would doubtless make the task less difficult, but, failing that, our duty is to arrange for some legislation which shall give our better and more ambitious students an opportunity of passing a dominion licensing-board (or whatever it may be called) which shall give the privilege of practising their profession not only in any part of their native country, but in any part of the world over which the British flag flies. Such a scheme need not interfere in any way with the autonomy of the provinces. Each may still retain its provincial board for the purpose of examining and issuing licenses to those candidates who are satisfied to practise their profession in the limited sphere of their own provinces. I think the legislators of this country will some day (and not far distant either) be induced to see that the system which at present obtains is unworthy of a great and growing country.

In conclusion, allow me to express the hope that the arrangements made by the executive committee for the entertainment of our guests may meet with appreciation and approval, and that the memories of the brief sojourn here may be all that is bright and happy. The loyalty and unanimity with which the profession throughout the dominion has co-operated with us in Montreal to make this meeting of the British Medical Association a success from every point of view, deserve and receive our heartiest thanks. We are also greatly indebted for the kind and ready assistance of the dominion government, the Quebec government, and the civic government of Montreal. Our hands have been strengthened and the cause we have so much at heart has been furthered by the active good will of the country's official representatives.

One word more: It is a good thing to be here to-day, in the midst of this great gathering so full of power and vigor. The fruits of such a gathering should be tangible, enduring, not ephemeral, not for to-day, but for all time. To our kinsmen from beyond the great seas let me express the earnest hope that in the future our kinship will be a more real and living thing than in the past. We are members of one great family, members one of another, in a peculiar and very real sense. Let that once be recognized, and the statesman's task will be an easy one. In more than words has Canada shown herself worthy of her high heritage, worthy of a part in the empire, worthy to share in its trials and its triumphs. We, who know her history, can say with well-founded confidence:

"So in the long hereafter this Canada shall be
The worthy heir of British power and British liberty;
Spreading the blessings of her sway to her remotest bounds,
While with the fame of her fair name a continent resounds.
True to her high traditions, to Britain's ancient glory,
Of patient saint and martyr, alive in deathless story;
Strong in their liberty and truth to shed from shore to shore
A light among the nations till nations are no more."

BRITISH MEDICINE IN GREATER BRITAIN.[1]

By WILLIAM OSLER, M.D., F.R.C.P.
PROFESSOR OF MEDICINE, JOHNS HOPKINS UNIVERSITY.

The Making of Greater Britain.—To trace successfully the evolution of any one of the learned professions would require the hand of a master, of one who, like Darwin, could combine the capacity for patient observation with philosophic vision. In the case of medicine the difficulties are enormously increased by the extraordinary development which belongs to the history of the present century. The rate of progress has been too rapid for us to appreciate, and we stand bewildered, and, as it were, in a state of intellectual giddiness, when we attempt to obtain a broad, comprehensive view of the subject. In a safer "middle flight" it is my purpose to dwell on certain of the factors which have moulded the profession in English-speaking lands beyond the narrow seas—of British medicine in Greater Britain. Even for this lesser task (though my affiliations are wide and my sympathies deep) I recognize the limitations of my fitness, and am not unaware that in my ignorance I shall overlook much which might have rendered less sketchy a sketch necessarily imperfect.

[1] The address in medicine delivered at the annual meeting of the British Medical Association, Montreal, September 1, 1897.

Evolution advances by such slow and imperceptible degrees that to those who are part of it the finger of time scarcely seems to move. Even the great epochs are seldom apparent to the participators. During the last century neither the colonists nor the mother country appreciated the thrilling interest of the long-fought duel for the possession of this continent. The acts and scenes of the drama, to them detached, isolated, and independent, now glide like dissolving views into each other, and in the vitascope of history we can see the true sequence of events. That we can meet here to-day, Britons on British soil in a French province, is one of the far-off results of that struggle. This was but a prelude to the other great event of the eighteenth century, the revolt of the colonies and the founding of a second great English-speaking nation—in the words of Bishop Berkeley's prophecy, "Time's noblest offspring."

Surely a unique spectacle, that a century later descendants of the actors of these two great dramas should meet in an English city in New France. Here the American may forget Yorktown in Louisberg, the Englishman Bunker Hill in Quebec, and the Frenchman both Louisberg and Quebec in Chataquay; while we Canadians, English and French, in a forgiving spirit, overlooking your unseemly quarrels, are only too happy to welcome you to our country, this land on which, and for which, you have so often fought. Once and only once before in the history of the world could such a gathering as this have taken place. Divided though the Greeks were, a Hellenic sentiment of extraordinary strength united them in certain assemblies and festivals. No great flight of imagination is required to picture a notable representation of our profession in the fifth century B.C. meeting in such a colonial town as Agrigentum under the presidency of Empedocles. Delegates from the mother cities, brilliant predecessors of Hippocrates of the stamp of Damocedes and Herodicus, delegates from the sister colonies of Syracuse and other Sicilian towns, from neighboring Italy, from far distant Massilia, and from still more distant Pauticapæum and Istria. And in such an assemblage there would have been men capable of discussing problems of life and mind more brilliantly than in many subsequent periods, in proportion as the pre-Hippocratic philosophers in things medical had thought more deeply than many of those who came after them.

We English are the modern Greeks, and we alone have colonized as they did, as free people. There have been other great colonial empires, Phœnician, Roman, Spanish, Dutch, and French, but in civil liberty and in intellectual freedom Magna Græcia and Greater Britain stand alone. The parallel so often drawn between them is of particular interest with reference to the similarity between the Greek settlements in Sicily and the English plantations on the Atlantic coast. Indeed, Freeman says, "I can never think of America without something suggesting Sicily, or of Sicily without something suggesting America." I wish to use the parallel only to emphasize two points, one of difference and one of resemblance. The Greek colonist took Greece with him. Hellas had no geographical bounds. "Massilia and Obia were cities of Hellas in as full a sense as Athens or Sparta." While the emigrant Britons changed their sky, not their character, in crossing the great sea, yet the home stayers had never the same feelings toward the plantations as the Greeks had toward the colonial cities of Magna Græcia. If, as has been shrewdly surmised, Professor Seely was Herodotus reincarnate, how grieved the spirit of the "Father of History" must have been to say of Englishmen, "Nor have we even now ceased to think of ourselves as simply a race inhabiting an island off the northern coast of the continent of Europe." The assumption of gracious superiority which, unless carefully cloaked, smacks just a little of our national arrogance, is apt to jar on sensitive colonial nerves. With the expansion of the empire, and the supplanting of a national by an imperial spirit, this will become impossible. That this sentiment never prevailed in Hellas, as it did later in the Roman empire, was due largely to the fact that in literature, in science, and in art the colonial cities of Greece early overshadowed the mother cities. It may be because the settlements of Greater Britain were things of slower growth that it took several generations and several bitter trials to teach a lesson the Greeks never had to learn.

The Greek spirit was the leaven of the old world, the workings of which no nationality could resist. Thrice it saved Western civilization, for it had the magic power of leading captivity captive, and making even captive conquerors the missionaries of culture. What modern medicine owes to it will appear later. "The love of science, the love of art, the love of freedom, vitally correlated to each other and brought into organic union," were the essential attributes of the Greek genius (Butcher). While we cannot claim for the Anglo-Saxon race all of these distinctions, it has in a high degree that one which in practical life is the most valuable, and which has been the most precious gift of the race to the world—the love of freedom—

> "Of freedom in her regal seat
> Of England."

It would carry one too far afield to discuss the difference between the native Briton and his children scattered so widely up and down the earth. In Canada, South Africa, Australia, and New Zealand types of the Anglo-Saxon race are developing which will differ as much from each other and from the English as the American does to-day from the original stock; but amid these differences can everywhere be seen those race qualities which have made us what we are—"courage, national integrity, steady good sense, and energy in work." At a future meeting of the association, perhaps in Australia, a professional Sir Charles Dilke, with a firm grasp on the subject, may deal with the medical problems of Greater Britain in a manner worthy of the address in medicine. My task, as I mentioned at the outset, is much less ambitious.

The Influence of Greece on Britain.—Could some one with full knowledge patiently analyze the characteristics of British medicine he would find certain national traits, sufficiently distinct for recognition. Three centuries cannot do very much—and that period has only just passed since the revival of medicine in England—but the local conditions of isolation, which have been singularly favorable to the development of special peculiarities in the national character, have not been without effect on the medical profession. I cannot do more than touch upon a few features, not distinctive but illustrative—features which will be useful as indicating the sources of influence upon Greater Britain in the past, and which may, perhaps, be suggestive as to lines of progress in the future.

Above the fireplace in Sir Henry Acland's study are three panelled portraits of Linacre, Sydenham, and Harvey; the scroll upon them reads: "*Literæ, Praxis, Scientia.*" To this great triumvirate, as to the fountainheads, we may trace the streams of inspiration which have made British medicine what it is to-day.

Linacre, the type of the literary physician, must ever hold a unique place in the annals of our profession. To him was due in great measure the revival of Greek thought in the sixteenth century in England, and in the last Harveian oration Dr. Payne has pointed out his importance as a forerunner of Harvey. He made Greek methods available; through him the art

of Hippocrates and the science of Galen became once more the subject of careful, first-hand study. Linacre, as Dr. Payne remarks, "was possessed from his youth till his death by the enthusiasm of learning. He was an idealist, devoted to objects which the world thought of little use." Painstaking, accurate, critical, hypercritical, perhaps, he remains to-day the chief literary representative of British medicine. Neither in Britain nor in Greater Britain have we maintained the place in the world of letters created for us by Linacre's noble start. It is true that in no generation since has the profession lacked a man who might stand unabashed in the temple at Delos; but, judged by the fruits of learning, scholars of his type have been more common in France and Germany. Nor is it to our credit that so little provision is made for the encouragement of these studies. For years the reputation of Great Britain in this matter was sustained almost alone by the great Deeside scholar, the surgeon of Banchory, Francis Adams, the interpreter of Hippocrates to English students. In this century he and Greenhill have well maintained the traditions of Linacre. Their work, and that of a few of our contemporaries, among whom Ogle must be specially mentioned, has kept us in touch with the ancients. But by the neglect of the study of the humanities, which has been far too general, the profession loses a very precious quality.

While in critical scholarship and in accurate historical studies British medicine must take a second place, the influence of Linacre, exerted through the Royal College of Physicians and the old universities, has given to the humanities an important part in education, so that they have moulded a larger section of the profession than in any other country. A physician may possess the science of Harvey and the art of Sydenham, and yet there may be lacking in him those finer qualities of heart and head which count for so much in life. Pasture is not everything, and that indefinable, though well understood, something which we know as breeding is not always an accompaniment of great professional skill. Medicine is seen at its best in men whose faculties have had the highest and most harmonious culture. The Lathams, the Watsons, the Pagets, the Jenners, and the Gairdners have influenced the profession less by their special work than by exemplifying those graces of life and refinements of heart which make up character. And the men of this stamp in Greater Britain have left the most enduring mark: Beaumont, Bovell, and Hodder in Toronto; Holmes, Campbell, and Howard in this city; the Warrens, the Jacksons, the Bigelows, the Bowditches, and the Shattucks in Boston; Bard, Hossack, Francis, Clark, and Flint in New York; Morgan, Shippen, Redman, Rush, Coxe, the elder Wood, the elder Pepper, and the elder Mitchell in Philadelphia —Brahmins all, in the language of the greatest Brahmin among them—Oliver Wendell Holmes—these, and men like unto them, have been the leaven which has raised our profession above the dead level of a business. The *literæ humaniores*, represented by Linacre, revived Greek methods, but the faculty at the end of the sixteenth and the beginning of the seventeenth centuries was in a slough of ignorance and self-conceit, and not to be aroused even by Moses and the prophets in the form of Hippocrates and the fathers of medicine.

In the pictures referred to Sydenham is placed between Linacre and Harvey, but science preceded practice, and Harvey's great Lumleian lectures were delivered before Sydenham was born. Linacre has been well called by Payne Harvey's intellectual grandfather. "The discovery of the circulation of the blood was the climax of that movement which began a century and a half before with the revival of Greek medical classics and especially of Galen" (Payne). Harvey returned to Greek methods and became the founder of modern experimental physiology and the great glory of British scientific medicine. The demonstration of the circulation of the blood remains in every detail a model research. I shall not repeat the ofttold tale of Harvey's great and enduring influence, but I must refer to one feature which, until lately, has been also a special characteristic of his direct successors in Great Britain. Harvey was a practitioner and a hospital physician. There are gossiping statements by Aubrey to the effect that "he fell mightily in his practice" after the publication of the "De Motu Cordis," and that his "therapeutic way" was not admired; but to these his practical success is the best answer. It is remarkable that a large proportion of all the physiological work of Great Britain has been done by men who have become successful hospital physicians and surgeons. I was much impressed by a conversation with Professor Ludwig in 1884. Speaking of the state of English physiology, he lamented the lapse of a favorite English pupil from science to practice; but he added, "while sorry for him, I am glad for the profession in England." He held that the clinical physicians of that country had received a very positive impress from the work of their early years in physiology and the natural sciences. I was surprised at the list of names which he cited—among them I remember Bowman, Paget, Savory, and Lister. Ludwig attributed this feature in part to the independent character of the schools in England, to the absence of the university element, so important in medical life in Germany, but, above all, to the practical character of the English mind, the better men preferring an active life in practice to a secluded laboratory career.

Thucydides it was who said of the Greeks that they possessed "the power of thinking before they acted and of acting too." The same is true in a high degree of the English race. To know first what has to be done, then to do it, comprises the whole philosophy of practical life. Sydenham (*Angliæ lumen*, as he has been well called) is the model practical physician of modern times. Linacre led Harvey back to Galen, Sydenham to Hippocrates. The one took Greek science, the other not so much Greek medicine as Greek methods, particularly intellectual fearlessness, and a certain knack of looking at things. Sydenham broke with authority and went to nature. It is an extraordinary fact that he could have been so emancipated from dogmas and theories of all sorts. He laid down the fundamental proposition, and acted upon it, that "all diseases should be described as objects of natural history." To do him justice we must remember, as Dr. John Brown says, "in the midst of what a mass of errors and prejudices, of theories actively mischievous, he was placed, at a time when the mania of hypothesis was at its height, and when the practical part of his art was overrun and stultified by vile and silly nostrums."

Sydenham led us back to Hippocrates; I would that we could be led oftener to Sydenham. How necessary to bear in mind what he says about the method of the study of medicine. "In writing, therefore, such a natural history of diseases, every merely philosophical hypothesis should be set aside, and the manifest and natural phenomena, however minute, should be noted with the utmost exactness. The usefulenss of this procedure cannot be easily overrated as compared with the subtle inquiries and trifling notions of modern writers, nor can there be a shorter, or, indeed, any other way of coming at the morbific causes, or of discovering the curative indications, than by a certain perception of the peculiar symptoms? By these steps and helps it was that the father of physic, the great Hippocrates, came to excel, his theory being no more than an exact description or view of nature. He found

that nature alone terminates diseases, and works a cure with a few simple medicines, and often enough with no medicine at all." Well, indeed, has a recent writer remarked: "Sydenham is unlike every previous teacher of the principles and practice of medicine in the modern world."

Sydenham—not Linacre or Harvey—is the model British physician, in whom were concentrated all these practical instincts upon which we lay such stress in the Anglo-Saxon character. The Greek faculty which we possess of thinking and acting has enabled us, in spite of many disadvantages, to take the lion's share in the great practical advances in medicine. The three greatest scientific movements of the century have come from Germany and France. Bichát, Laennec, and Louis laid the foundation of modern clinical medicine; Virchow and his pupils of scientific pathology; while Pasteur and Koch have revolutionized the study of the causes of disease; and yet the modern history of the art of medicine could almost be written in its fulness from the records of the Anglo-Saxon race. We can claim almost every practical advance of the very first rank—vaccination, anæsthesia, preventive medicine, and antiseptic surgery—the "captain jewels in the carcanet" of the profession, beside which can be placed no others of equal lustre.

The Influence of Authority in Medicine.—One other lesson of Sydenham's life needs careful conning. The English Hippocrates, as I said, broke with authority. His motto was:

> "Thou, Nature, art my goddess, to thy law
> My services are bound."

Undue reverence for authority as such, a serene satisfaction with the *status quo*, and a fatuous objection to change, have often retarded the progress of medicine. In every generation, in every country, there had been, and ever will be, *laudatores temporis acti*, in the bad sense of that phrase, not a few of them men in high places, who have lent the weight of a complacent conservatism to bolster up an ineffectual attempt to stay the progress of new ideas. Every innovator from Harvey to Lister has been made to feel its force. The recently issued life of Thomas Wakley is a running commentary on this spirit, against the pricks of which he kicked so hard and so effectually. But there are signs of a great change. The old universities and the colleges, once the chief offenders, have been emancipated, and remain no longer, as Gibbon found them, steeped in port and prejudice. The value of authority *per se* has lessened enormously, and we of Greater Britain have perhaps suffered as the pendulum has swung to the other extreme. Practice loves authority, as announced in "the general and perpetual voice of men" (Hooker). Science must ever hold with Epicharmus that a judicious distrust and a wise scepticism are the sinews of the understanding. And yet the very foundations of belief in almost everything relating to our art rest upon authority. The practitioner cannot always be the judge, the responsibility must often rest with the teachers and investigators, who can learn only in the lessons of history the terrible significance of the word.

In the treatment of fever the fetters of a thousand years were shattered by Sydenham—shattered only to be riveted anew. How hard was the battle in this century against the entrenched and stubborn foe! Listen to the eloquent pleadings of Stokes, pleading, as did Sydenham, against authority, and against the bleedings, the purgings, and sweatings of fifty years ago. "Though his hair be gray, and his authority high, he is but a child in knowledge and his reputation an error. On a level with a child, so far as correct appreciation of the great truths of medicine is concerned, he is very different in other respects, his powers of doing mischief are greater; he is far more dangerous. Oh! that men would stoop to learn, or at least cease to destroy." The potency of human authority among "the powers that be" was never better drawn than by the judicious Hooker in his section on this subject: "And this not only with the 'simpler sort,' but the learneder and wiser we are, the more such arguments in some cases prevail with us. The reason why the simpler sort are moved with authority is the conscience of their own ignorance; whereby it cometh to pass that, having learned men in admiration, they rather fear to dislike them than know wherefore they should allow and follow their judgments. Contrariwise with them that are skilful, authority is much more strong and forcible; because they only are able to discern how just cause there is why to some men's authority so much should be attributed. For which cause the name of Hippocrates (no doubt) were more effectual to persuade even such men as Galen himself than to move a silly empiric."[1]

Sydenham was called "a man of many doubts," and therein lay the secret of his great strength.

Medicine in America to 1820.—Turning now to the main question of the development of this British medicine in Greater Britain, I must at once acknowledge the impossibility of doing justice to it. I can indicate only a few points of importance, and I must confine my remarks chiefly to the American part of Greater Britain.

We may recognize three periods, corresponding to three distinct waves of influence: the first from the early migrations to about 1820; the second from about 1820 to 1860; and the third from about 1860 to the present time.

The colonial settlements were contemporaneous with the revival of medicine in England. Fellow-students of Harvey at Cambridge might have sailed in the *Mayflower* and the *Arbella*. The more carefully planned expeditions usually enlisted the services of a well-trained physician, and the early records, particularly of the New England colonies, contain many interesting references to these college-bred men. Giles Firman, who settled in Boston in 1632, a Cambridge man, seems to have been the first to give instruction in medicine in the new world. The parsons of that day had often a smattering of physic, and illustrated what Cotton Mather called an "angelical conjunction." He says: "Ever since the days of Luke, the Evangelist, skill in physic has been frequently professed and practised by persons whose more declared business was the study of divinity." Firman himself finding physic "but a meane helpe," took orders. These English physicians in the New England colonies were scholarly, able men. Roger Chillingworth, in Hawthorne's "Scarlet Letter," has depicted them in a sketch of his own life: "Made up of earnest, studious, thoughtful, quiet years, bestowed faithfully for the increase of knowledge; faithfully, too, for the advancement of human welfare; men thoughtful for others, caring little for themselves, kind, just, true, and of constant if not warm affections"—a singularly truthful picture of the old colonial physician.

Until the establishment of medical schools—University of Pennsylvania, 1763; King's College (afterwards Columbia), 1767; and Harvard, 1782—the supply of physicians for the colonies came from Great Britain, supplemented by men trained under the old apprentice system, and of colonists who went to Edinburgh, Leyden, and London for their medical education. This latter group had a most powerful effect in moulding professional life in the prerevolutionary period. They were men who had enjoyed not alone the instruction, but often the intimate friendship of the great English and European physicians. Morgan,

[1] "Ecclesiastical Polity," Bk. ii. vii. 2.

Rush, Shippen, Bard, Wistar, Hossack, and others had received an education comprising all that was best in the period, and had acquired the added culture which can come only from travel and wide acquaintance with the world. Morgan, the founder of the medical school of the University of Pennsylvania, was away seven years, and before returning had taken his seat as a corresponding member of the French Academy of Surgery, besides having been elected a fellow of the Royal Society. The war of independence interrupted temporarily the stream of students, but not the friendship which existed between Cullen and Fothergill and their old pupils in America. The correspondence of these two warm friends of the colonies testifies to the strong professional intimacy which existed at the time between the leaders of the profession in the old and new worlds. But neither Boerhaave, Cullen, nor Fothergill stamped colonial medicine as did the great Scotchman, John Hunter. Long weary centuries separated Harvey from Galen; not a century elapsed from the death of the great physiologist to the advent of the man in whose phenomenal personality may be seen all the distinctive traits of modern medicine, and the range of whose mighty intellect has had few, if any, equals since Aristotle. Hunter's influence on the profession of this continent, so deep and enduring, was exerted in three ways. In the first place, his career as an army surgeon, and his writings on subjects of special interest to military men, carried his work and ways into innumerable campaigns in the long French wars and the war of independence. Hunter's works were reprinted in America as early as 1791 and 1793. In the second place, Hunter had a number of most distinguished students from the colonies, among whom were two who became teachers of wide reputation. William Shippen, the first professor of anatomy in the University of Pennsylvania, lived with Hunter on terms of the greatest intimacy. He brought back his methods of teaching, and some measure of his spirit. With the exception of Hewson and Home, Hunter had no more distinguished pupil than Philip Syng Physick, who was his house surgeon at St. George's Hospital and his devoted friend. For more than a generation Physick had no surgical compeer in America, and enjoyed a reputation equalled by no one save Rush. He taught Hunterian methods in the largest medical school in the country, and the work of his nephew (Dorsey) on surgery is very largely Hunter modified by Physick. But in a third and much more potent way the great master influenced the profession of this continent. Hunter was a naturalist to whom pathological processes were only a small part of a stupendous whole, governed by law, but which could never be understood until the facts had been accumulated, tabulated, and systematized. By his example, by his prodigious industry, and by his suggestive experiments he led men again into the old paths of Aristotle, Galen, and Harvey. He made all thinking physicians naturalists; he lent a dignity to the study of organic life, and re-established a close union between medicine and the natural sciences. Both in Britain and Greater Britain he laid the foundation of the great collections and museums, particularly those connected with the medical schools. The Wistar-Horner and the Warren Museums originated with men who had been greatly influenced by Hunter. He was, moreover, the intellectual father of that interesting group of men on this side of the Atlantic, who, while practising as physicians, devoted much time and labor to the study of natural history. In the latter part of the last century, and during the first thirty years of this, the successful practitioner was very often a naturallist.

I wish that time permitted me to do justice to the long list of men who have been devoted naturalists, and who have made contributions of great value. Benjamin Smith Barton, David Hossack, Jacob Bigelow, Richard Harland, John D. Godman, Samuel George Morton, John Collins Warren, Samuel L. Mitchell, J. Aiken Meigs, and many others have left the records of their industry in their valuable works and in the transactions of the various societies and academies. In Canada many of our best naturalists have been physicians, and collections in this city testify to the industry of Holmes and McCullough. I was regretting the humanities a few minutes ago, and now I have to mourn the almost complete severance of medicine from the old natural history. To a man the most delightful recollections of whose studentship are the Saturdays spent with a preceptor who had a Hunterian appetite for specimens—anything from a trilobite to an acarus—to such a one across the present brilliant outlook comes the shadow of the thought that the conditions of progress will make impossible again such careers as those of William Kitchen Parker and William Carmichael McIntosh.

Until about 1820 the English profession of this continent knew little else than British medicine. After this date in the United States the ties of professional union with the old country became relaxed, owing in great part to the increase in the number of home schools, and in part to the development of an American literature. To 1820, one hundred and fourteen native medical books of all kinds had been issued from the press, and one hundred and thirty-one reprints and translations, the former English, the latter almost exclusively French (Billings). Turning for a few minutes to the conditions of the profession in Canada during this period, I regret that I cannot speak of the many interesting questions relating to the French colonies. I may mention, however, that with the earliest settlers physicians had come, and among the Jesuits, in their devoted missions, there are records of *donnés* (laymen attached to the service) who were members of the profession. One of these, René Goupil, suffered martyrdom at the hands of the Iroquois.[1]

Between the fall of Quebec in 1759 and 1820, the English population had been increased by the settlement of Upper Canada, chiefly by United Empire Loyalists from the United States, and after the war of 1812 by settlers from the old country. The physicians in the sparsely settled districts were either young men who sought their fortunes in the new colony, or were army surgeons who had remained after the revolutionary war or the war of 1812. The military element gave for some years a very distinctive stamp to the profession. These surgeons were men of energy and ability, who had seen much service and were accustomed to order, discipline, and regulations. Sabine, in his "History of the Loyalists," refers to the Tory proclivities of the doctors, and says that they were not so much disturbed as the lawyers and clergymen. Still a good many of them left their homes "for conscience sake;" and Canniff, in his "History of the Profession in Upper Canada," gives a list of those known to have been among the United Empire Loyalists. The character of the men who controlled the profession of the new colony is well shown by the proceedings of the medical board, which was organized in 1819. Drs. Macaulay and Widmer, both army surgeons, were the chief members. The latter, who has well been termed the father of the profession in Upper Canada, a man of the very highest character, did more than any one else to promote the progress of the profession, and throughout his long career his efforts were always directed in the proper channels. In looking through Canniff's most valuable work one is much impressed by the sterling worth and mettle of the old army surgeons, who in these early days formed

[1] Parkman: "Jesuits in North America."

the larger part of the profession. The minutes of the medical board indicate with what military discipline the candidates were examined, and the percentage of rejections has probably never been higher in the history of the province than it was in the first twenty years of the existence of the board.

One picture on the canvas of those early days lingers in the memory, illustrating many of the most attractive features of a race which has done much to make this country what it is to-day. Widmer was the type of the dignified old army surgeon, scrupulously punctilious, and in every detail regardful of the proprieties of life. "Tiger" Dunlop may be taken as the very incarnation of that restless, roving spirit which has driven the Scotch broadcast upon the world. After fighting with the Connaught Rangers in the war of 1812, campaigning in India, clearing the Sangur of tigers—hence his sobriquet "Tiger"—lecturing on medical jurisprudence in Edinburgh, writing for *Blackwood*, editing the *British Press* and the *Telescope*, introducing Beck's "Medical Jurisprudence" to English readers, and figuring as director and promotor of various companies, this extraordinary character appears in the young colony as "Warden of the Black Forest" in the employ of the Canada Company. His life in the backwoods at Gairbraid, his "Noctes Ambrosianæ Canadenses," his famous "Twelve Apostles," as he called his mahogany liquor stand (each bottle a full quart), his active political life, his remarkable household, his many eccentricities—are they not all portrayed to the life in the recently issued "In the Days of the Canada Company"?

America: 1820—1860.—Turning now to the second period, we may remark in passing that the nineteenth century did not open very auspiciously for British medicine. Hunter had left no successor, and, powerful as had been his influence, it was too weak to stem the tide of abstract speculation with which Cullen, Brown, and others flooded the profession. No more sterile period exists than the early decades of this century. Willan, a great naturalist in skin diseases, with a few others, save it from utter oblivion. The methods of Hippocrates, of Sydenham, and of Hunter had not yet been made available in every-day work. The awakening came in France, and such an awakening! It can be compared with nothing but the renaissance in the sixteenth and seventeenth centuries, which gave us Vesalius and Harvey. "Citizen" Bichât and Broussais led the way, but Laennec really created clinical medicine as we know it to-day. The discovery of auscultation was only an accident—of vast moment it is true—in a systematic study of the correlation of symptoms with anatomical changes. Louis, Andral, and Chomel extended the reputation of the French school, which was maintained to the full until the sixth decade, when the brilliant Trousseau ended a long line of Paris teachers, whose audience had been worldwide.

The revival of medicine in Great Britain was directly due to the French. Bright and Addison, Graves and Stokes, Forbes and Marshall Hall, Latham and Bennett were profoundly affected by the new movement. In the United States, Anglican influence did not wane until after 1820. Translations of the works of Bichât appeared as early as 1802, and there were reprints in subsequent years, but it was not until 1823 that the first translation of Laennec—a reprint of Forbes' edition—was issued. Broussais' works became very popular in translations after 1830, and in the journals from this time on the change of allegiance became very evident. But men rather than books diverted the trend of professional thought.

After 1825 American students no longer went to Edinburgh and London, but to Paris, and one can say that between 1830 and 1860 every teacher and writer of note passed under the Gallic yoke. The translations of Louis' works and the extraordinary success of his American pupils—a band of the ablest young men the country has ever seen—added force to the movement. And yet this was a period in which American medical literature was made up largely of pirated English books, and the systems, encyclopædias, and libraries, chiefly reprints, testify to the zeal of the publishers. Stokes, Graves, Watson, Todd, Bennett, and Williams furnished Anglican pap to the sucklings, as well as strong meat to the full grown. In spite of the powerful French influence the textbooks of the schools were almost exclusively English.

In Canada the period from 1820 to 1860 saw the establishment of the English universities and medical schools. In Montreal the agencies at work were wholly Scotch. The McGill Medical School was organized by Scotchmen, and from its inception has followed closely Edinburgh methods. The Paris influence, less personal, was exerted chiefly through English and Scotch channels. The Upper Canada schools were organized by men with English affiliations and the traditions of Guy's, St. Bartholomew's, St. Thomas', St. George's, and of the London Hospital, rather than those of Edinburgh, have prevailed in Toronto and Kingston.

The local French influence on British medicine in Canada has been very slight. In the early decades of the century, when the cities were smaller, and the intercourse between the French and English was somewhat closer, the reciprocal action was more marked. At that period English methods became somewhat the vogue among the French; several very prominent French Canadians were Edinburgh graduates. Attempts were made in the medical journals to have communications in both languages, but the fusion of the two sections of the profession was no more feasible than the fusion of the two nationalities, and the development has progressed along separate lines.

America: 1860–1897.—The third period dates from about 1860, when the influence of German medicine began to be felt. The rise of the Vienna school was for a long time the only visible result in Germany of the French renaissance. Skoda, the German Laennec, and Rokitansky, the German Morgagni, influenced English and American thought between 1840 and 1860, but it was not until after the last date that Teutonic medicine began to be felt as a vitalizing power, chiefly through the energy of Virchow. After the translation of the "Cellular Pathology" by Chance (1860) the way lay clear and open to every young student who desired inspiration. There had been great men in Berlin before Virchow, but he made the town on the Spree a Mecca for the faithful of all lands. From this period we can date the rise of German influence in the profession of this continent. It came partly through the study of pathological histology under the stimulus given by Virchow, and partly through the development of the specialties, particularly diseases of the eye, of the skin, and of the larynx. The singularly attractive courses of Hebra, the organization on a large scale in Vienna of a system of graduate teaching designed especially for foreigners, the remarkable expansion of the German laboratories, combined to divert the stream of students from France. The change of allegiance was a deserved tribute to the splendid organization of the German universities, to the untiring zeal and energy of their professors, and to their single-minded devotion to science for its own sake.

Medicine in Australasia.—In certain aspects the Australasian settlements present the most interesting problems of Greater Britain. More homogeneous, thoroughly British, isolated, distant, they must work out their destiny with a less stringent environment than,

for example, surrounds the English in Canada. The traditions are more uniform, and, of whatever character, have filtered through British channels. The professional population of native-trained men is as yet small, and the proportion of graduates and licentiates from the English, Scotch, and Irish colleges and boards guarantees the dominance of old-country ideas. What the maturity will show cannot be predicted, but the vigorous infancy is full of "crescent promise." On looking over the files of Australian and New Zealand journals one is impressed with the monotonous similarity of the diseases in the antipodes to those of Great Britain and of this continent. Except in the matter of parasitic affections and snake bites, the nosology presents few distinctive qualities. The proceedings of the four intercolonial congresses indicate a high level of professional thought. In two points Australia has not progressed as other parts of Greater Britain. The satisfactory regulation of practice, so early settled in Canada, has been beset with many difficulties. Both in the United States and in Australia the absence of the military element, which was so strong in Canada, may, in part at least, account for the great difference which has prevailed in this matter of the State license. The other relates to the question of ethics, to which one really does not care to refer, were it not absolutely forced upon the attention in reading the journals. Elsewhere professional squabbles, always so unseemly and distressing, are happily becoming very rare, and in Great Britain and on this side of the water we try at any rate to wash our dirty linen at home. In the large Australian cities differences and dissensions seem lamentably common. Surely they must be fermented by the atrocious system of election to the hospitals, which plunges the entire profession every third or fourth year into the throes of a contest in which the candidates have to solicit the suffrages of from two thousand to four thousand voters. Well indeed might Dr. Batchelor, in his address to the fourth intercolonial congress, say: "It is a scandal that in any British community, much less in a community which takes pride in a progressive spirit, such a pernicious system should survive for an hour."

Medicine in Hindustan.—Of India, of "Vishnuland," what can one say in a few minutes? Three thoughts at once claim recognition. Here, in the dim dawn of history, with the great Aryan people, was the intellectual cradle of the world. To the Hindus we owe a debt which we can at any rate acknowledge; and even in medicine many of our traditions and practices may be traced to them, as may be gathered from that most interesting "History of Aryan Medical Science," by the Thakore Sahib of Gondal.

Then there arises the memory of the men who have done so much for British medicine in this great empire. Far from their homes, far from congenial surroundings, and far from the stimulus of scientific influences, Annesley and Ballingall, Twining, Morehead, Waring, Parkes, Cunningham, Lewis, Vandyke Carter, and many others have nobly upheld the traditions of Harvey and of Sydenham. On the great epidemic diseases how impoverished would our literature be in the absence of their contributions! But then there comes the thought of "the little done, the undone vast" when one considers the remarkable opportunities for study which India has presented. Where else in the world is there such a field for observation in cholera, leprosy, dysentery, the plague, typhoid fever, malaria, and in a host of other less important maladies? And what has the British government done toward the scientific investigation of the diseases of India? Until recently little or nothing, and the proposal to found an institute for the scientific study of disease has actually come from the native chiefs. The work of Dr. Hankin and of Professor Haffkine, and the not unmixed evil of the brisk epidemic of plague in Bambay, may arouse the officials to a consciousness of their shortcomings. While sanitary progress has been great, as shown in a reduction of the mortality from sixty-nine per mille before 1857 to fifteen per mille at present, many problems are still urgent, as may be gathered from Dr. Harvey's presidential address in the "Proceedings of the Indian Medical Congress." That typhoid fever can be called the "scourge of India," and that the incidence of the disease should remain so high among the troops, point to serious sanitary defects as yet unremedied. As to the prevalence of venereal disease among the soldiers, an admission of nearly five hundred per mille tells its own tale. On reading the journals and discussions one gets the impression that things are not as they should be in India. There seems to be an absence of proper standards of authority. Had there been in each presidency during the past twenty years well-equipped government laboratories in charge of able men, well trained in modern methods, the contributions to our knowledge of epidemic diseases might have been epoch making, and, at any rate, we should have been spared the crudeness which is evident in some of the work (particularly in that upon malaria) of zealous but badly trained men.

The Future of Medicine in Greater Britain.—In estimating the progress of medicine in the countries comprising Greater Britain, the future rather than the present should be in our minds. The strides which have been taken during the past twenty years are a strong warrant that we have entered upon a period of exceptional development. When I see what has been accomplished in this city in the short space of time since I left I can scarcely credit my eyes. The reality exceeds the utmost desires of my dreams. The awakening of the profession in the United States to a consciousness of their responsibilities and opportunities has caused unparalleled changes, which have given an impetus to medical work which has already borne a rich harvest. Within two hundred years who can say where the intellectual centre of the Anglo-Saxon race will be? The mother country herself has become an intellectual nation of the first rank only within a period altogether too short to justify a prediction that she has reached the zenith. She will probably reverse the history of Hellas, in which the mental superiority was at first with the colonies. At the end of the next century ardent old-world students may come to this side, "as o'er a brook," seeking inspiration from great masters, perhaps in this very city; or the current may turn toward the schools of the great nations of the South. Under new and previously unknown conditions the Africander, the Australian, or the New Zealander may reach a development before which even the "glory that was Greece" may pale. Visionary as this may appear, it is not one whit more improbable to-day than would have been a prophecy made in 1797 that such a gathering as the present would be possible within a century on the banks of the St. Lawrence.

Meanwhile, to the throbbing vitality of modern medicine the two great meetings held this month, in lands so widely distant, bear eloquent testimony. Free, cosmopolitan, no longer hampered by the dogmas of schools, we may feel a just pride in a profession almost totally emancipated from the bondage of error and prejudice. Distinction of race, nationality, color, and creed are unknown within the portals of the temple of Æsculapius. Dare we dream that this harmony and cohesion so rapidly developing in medicine, obliterating the strongest lines of division, knowing no tie of loyalty but loyalty to truth—dare we hope, I say, that in the wider range of human affairs a similar solidarity may ultimately be reached? Who can say

that the forges of time will weld no links between man and man stronger than those of religion or of country? Some son of Beor, touched with a prophetic vision, piercing the clouds which now veil the eternal sunshine of the mountain top, some spectator of all time and all existence (to use Plato's expression) might see in this gathering of men of one blood and one tongue a gleam of hope for the future, of hope, at any rate, that the great race, so dominant on the earth to-day, may progress in the bonds of peace—a faint glimmer, perhaps, of the larger hope of humanity of the day when "the common sense of most shall hold a fretful world in awe." But these, I fear, are the dreams of the closet student who knows not the world nor its ways. There remains for us, Greater Britons, of whatsoever land, the bounden duty to cherish the best traditions of our fathers, and particularly of the men who gave to British medicine its most distinctive features: of the men, too, who found for us the light and liberty of Greek thought—Linacre, Harvey, and Sydenham—those "ancient founts of inspiration," and models for all time in literature, science, and practice.

ADDRESS IN SURGERY.[1]

BY W. MITCHELL BANKS, M.D. Lond.,

[illegible]

The Surgeon of Old in War.—I am indeed greatly honored by having to deliver to you to-day an address in surgery. Fortunately for me the title is a wide one, and I shall take advantage of that fact to diverge from the strict consideration of surgical disease, and shall offer you instead a brief sketch of some of the most notable work done of old by a body of members of our profession who have never received their due reward—those, namely, who have devoted their lives to the succor of the sick and the wounded in war.

Military Surgeons in the Roman Army.—Twelve months ago my friend, Dr. Barnes, of Carlisle, ex-president of this association, made me acquainted with a remarkable paper by the late Sir James Simpson, entitled "Was the Roman Army Provided with Medical Officers?"—a paper exhibiting such profound learning, so charmingly written, and so little known that I need not make any apology for acquainting you with some of its chief points of interest.

The most careful investigations have failed to make out from their writings whether the Romans regularly appointed physicians and surgeons to their armies or not, although nearly every other question relating to their military organization has been treated of, sometimes very fully. Curiously enough, what little information we possess on the subject comes mainly from mortuary or from votive tablets. Borcovicus, in Northumberland—now called Housesteads—was one of the principal stations on the line of Hadrian's wall. Here, about seventy years ago, was found a monumental tablet, now in the Newcastle Museum. On it is the following inscription:

[illegible]
MEDICO
[illegible]

The first Tungrian cohort is known to have been present at the battle of the Mons Grampius, and to have served at Castlecary, at Cramond near Edinburgh, in Cumberland, and at Housesteads. The tablet is highly ornamented, and antiquarians hold that a rabbit and round bucklers carved in the upper part, which are emblems of Spain, show that the young military doctor was probably a native of that country. From various works treating of Roman inscriptions Simpson was enabled to find that four more tablets, in which surgeons of cohorts are mentioned, existed. They were found at Rome. One of them is a votive tablet, the inscription upon which intimates that it was dedicated by Sextus Titius Alexander to Æsculapius and to the safety of his fellow-soldiers. It was cut in the year of the consulship of F. Flavius Sabinus, which is known to have been A.D. 83. As the Roman legion consisted of ten cohorts, it is interesting to know that not only were medical officers attached to each cohort, but also one was attached to the legion—a sort of surgeon-colonel, as we should call him nowadays. Three tablets have been discovered in which the *medicus legionis* is mentioned. One found at Verona was a tablet raised by Scribonia Faustina to her dearest husband, J. Caelius Arrianus, medical officer to the second Italian legion, who died at the age of forty-nine years and seven months. Furthermore, Simpson routed out of Mommsen's Latin inscriptions of Naples a tablet, now in the Dresden collection, which was found in the Elysian fields near Baiæ, close to the Portus Julius, which was the station of a division of the imperial fleet. The inscription tells that M. Satrius Longinus, *medicus duplicatorius* to the trireme *Cupid*, and the heirs of those freed by Julia Veneria erected the tablet to the manes of that deserving lady. The term *duplicatorius* means that by reason of long or meritorius service he was entitled to double pay and rewards. These little gleanings from Simpson's paper show what an interesting one it is, and one is astonished at the labor that must have been expended in digging up the information contained in it.

Ambroise Paré.—Hundreds of years went past before there came upon the scene any military surgeon of note, but when he did appear he was a man of transcendent merit—the illustrious Ambroise Paré. From 1517 to 1590, for seventy-three years, he lived a long and incessantly active life, the contemporary of Vesalius, the immediate predecessor of Harvey. We have only time to glance at the soldier-surgeon side of Paré's life. For over thirty years he followed the wars under four kings of France—Henry the Second, Francis the Second, Charles the Ninth, and Henry the Third, with intervals of a few years at home in Paris. Perpignan, Metz, Verdun, Rheims, Hesdin (where he was taken prisoner and had to write to his wife for his ransom), St. Quentin, La Fère, Amiens, the taking of Rouen, Dreux, Moncontour—these are but some of the bloody battles and sieges at which he was present. Through them all his humanity, his love of his profession, his independent character, and his jovial, frank disposition carried him safe, and made for the son of the poor country joiner warm friends among the greatest and noblest warriors of France. Even that miserable monster, Charles the Ninth, loved the Huguenot surgeon, and when the awful day of St. Bartholomew came Paré was spared to tend his wretched master through the brief term of agonized and remorseful life that was given him. The description in Dumas' novel, the "Two Dianas," of the wound of the famous warrior, Duke of Guise, where the lance entered above the right eye and came out between the nucha and the left ear, breaking short off, and how Paré lugged it out, with the chance that when it did come, one terrible gush of blood would finish his illustrious patient's life and his own career at the same moment—the picture of all this is real history.

Amid all the splendid work, both anatomical and surgical, which Paré did, the application of the prin-

[1] Delivered at the [illegible] Meeting of the British Medical Association at Montreal, September 2, 1897.

ciple of the ligature to bleeding arteries is of course that with which his name will be forever associated. In this day of grace it is impossible for us to imagine the horrors that awaited a wretched man so soon as his limb was cut off and the process of stopping the bleeding began. Think of the raw and exquisitely sensitive stump exposed to the red-hot cautery or plunged into boiling pitch! For this frightful treatment Paré substituted the ligature, which in our own day, employed in the form of an aspetic animal material which the tissues quietly absorb, has practically reached the pitch of perfection. In his time, too, there was a fixed belief that the danger from gunshot wounds arose from the poison of the gunpowder conveyed on the bullet. To destroy this poison the treatment was to pour into the wound boiling oil in which elderwood bark had been stewed. On one occasion, not having this infernal concoction at hand, Paré used a cold mixture of yolk of egg, oil of roses, and turpentine to his wounded soldiers. He passed a sleepless night from dread that this would injure those to whom it had been applied, and his delight next day was proportionately great when he found that they had had but little pain, while their wounds were free from inflammation and swelling. This was his panacea for wounds ever afterward. There are of course persons who wish to make out that he was not original in the matter of the ligature. He himself says this about it: "Taught me as I interpret it by the suggestion of some good angel, for I neither learnt it of my masters nor of any other man. And thus I wish all chirurgions to doe. For it is not in our art, as it is in civill affaires, that prescription, law, or authority should prevail over right reason." But these cavillers have doubtless never heard of an ancient proverb which says that there is nothing new under the sun. In spite of them the world will ever believe in a glorious trio—Paré, the Frenchman, who invented the ligature; Morton, the American, who discovered anæsthetics; and Lister, the Englishman, who introduced antiseptics. In the fulness of years, possessed of affluence and surrounded by friends, died Paré, the whilom poor barber-chirurgeon, now a councillor of state and surgeon-in-chief to the king. One final touch will perhaps reveal a sentiment that permeated and guided his every labor. On one occasion, after the successful treatment of a wounded officer, he made this wise and reverent remark, afterward adopted as his motto: "*Je le pansay; Dieu le guarist*"—"I treated him; God cured him."

Robert Clowes.—Coming to England, a surgeon who saw no little fighting was Robert Clowes, who was born somewhere about 1540 and died in 1604. He served in France in the army commanded by the Earl of Surrey, and was afterward for several years in the navy. He then began practice in London, and was made surgeon to St. Bartholomew's and Christ's Hospitals. But, after being about fourteen years in civil practice, he was despatched by Queen Elizabeth's orders into the Low Countries to attend upon the Earl of Leicester, commander of Her Majesty's forces. He was at Zutphen when Sir Philip Sydney was killed. His last piece of service was a glorious one, he being with our fleet that defeated the Spanish armada. It is told of him that he always kept beside him his military surgical chest with the bear and ragged staff of his old chief Leicester on the lid. He finally settled down once more in London, where he was very successful in practice, and was made surgeon to the queen. He wrote several works in English, of which the most important is entitled "A profitable and necessarie Booke of Observations for all those that are burned with the flame of gunpowder, &c., and also for curing of wounds made with musket and caliver shot, and other weapons of war commonly used at this day both by sea and land." A good half of this treatise is occupied with a record of surgical cases of note which he had treated, and this renders the work very entertaining, inasmuch as we get an accurate and positive knowledge of everything that was done for a wounded man in those days, while there are numerous little side touches very characteristic of life at the time it was written. He tells us, for instance, of "The cure of one Master Andrew Fones, a merchant of London, which, being in a ship at the sea was set upon by the Flushingers, in which fight he was very dangerously wounded with gunshot." There is "The Cure of one Henry Rhodes, one of the waiters at the Custom House, he being upō the river of Thames a skirmishing with his peece, and by reason the peece had certain flaws in it, did breake into many peeces, and made a great wound upon his chin, and carried away a good part of the manduble and the teeth withall; moreover, it did rend his hand greatly: all which I cured without maime or deformitie." There is "An observation for the cure of the master of a Hoy that had both his legs fractured and broken into many peeces with an iron bullet, shot out of a great basse or harquebusse of crocke at the sea by a Pyrat or sea rover." These few titles will give you an idea of Clowes' clinical cases. The importance which attaches to them, and the reason why they constitute a distinct advance in the science of surgery is that the author gives his actual experiences and tells us what he did to his patients, whereas at that period the tendency was to write endless commentaries on ancient writers, to whose every dictum the blindest and most unreasoning respect was paid.

Peter Lowe.—Contemporary with Clowes was a most interesting character—Maister Peter Lowe—who was born in Scotland about 1550, and lived some sixty or sixty-five years, reaching well into the seventeenth century. Like many of his countrymen, he went to France when very young, where he lived, for some say ten, some twenty years. Then he returned to Glasgow, where he lived and died a citizen of much renown, having obtained in 1599 from King James the Sixth a charter for the Faculty of Physicians and Surgeons of Glasgow, which he thus founded. A few years ago Dr. Finlayson published a most charming account of Maister Peter.

His most important work is termed "A Discourse of the whole art of chirurgery, compiled by Peter Lowe, Scottishman, Doctor in the Faculty of Chirurgerie at Paris, and ordinary Chyrurgion to the French King and Navarre." The first edition dated from 1597, and is one of the earliest, if not the very earliest, work embracing the whole art of surgery published in English. It is clear that Lowe must have seen a good deal of military service abroad, being "Chirurgion Major to the Spanish regiments two years at Paris, and since that time following the king of France my maister in the warrs." In his day, as we have seen, the surgical world was still greatly exercised about gunshot wounds and burning by gunpowder, as it was believed that they were injuries of quite a peculiar and very poisonous character. Lowe, however, treats of them with great good sense. Thus: "Of Wounds done by Gun-shot.—These wounds come indifferently to all parts of our body whereof there are divers opinions; some think that there is a venenosity in the powder, and burning in the bullet, which is false, for the things whereof the powder is ordinarily made, as Brimstone, Saltpeter, coales of divers sorts of trees, Water, Wine and Aquavitæ, have no venenosity in them; likewise there is no burning in the bullet, for if the bullet of lead being shot a great way, should burne, through heat would be melted itself. I have cured divers within these thirty yeares of divers nations which have followed the warres in Fraunce

and other cuntries, in the which I have found no more difficulty than in any other contused wounds." Here, again, we have a most important advance made by a military surgeon, for only those who are acquainted with the medical literature of Lowe's time can understand the ridiculous views then held about gunshot wounds, and the dreadful consequences to the patients which followed from them.

We have seen that Paré lived between 1517 and 1590, and that Peter Lowe was in France between 1570 and 1580; consequently, he probably learned all about the ligature for the arrest of hemorrhage. When treating of amputations he describes the whole process of the operation up to the removal of the limb. Then he says: "One of the Assisters shall put the extreamities of his fingers on the great vains and arteries to stay them from bleeding till the Chyrurgion either knit or cauterize them one after another. Where there is putrefaction we stay the flux of blood by Cauters actuals, and where there is no putrefaction, malignitie nor humour venomous we use the legator." He narrates the case of a certain valiant Captain Boyle of the Spanish troops, whom he, in the capacity of chyrurgion-major to the regiment, was summoned to treat for an "aneurisme on the right side of his cragge." Lowe ordered it to be let alone, "but the captain sent for an ignorant Barbor who did open the swelling with a Launcet, which being done, the spirit and bloud came forth with such violence that the Captain died in fewe howers after." Having duly castigated the Ignorants who do such things, Lowe observes that his treatment for such cases is first to draw blood in both arms, and then to apply on the tumor "Rec, Pulveris subtilissimi boli arminici, sanguis draconis, myrtilorum, lapidis calaminaris in aceto extincti, absinthii ad unc. cum cerato refrigerantis Galeni quantum sufficit, fiat unguentum." Curious to note how, even in men of distinct ability like Lowe, a complete ignorance of pathology dragged them into the perpetration of the silliest empiricism.

Woodall's "Viaticum."—In 1628 appeared the first work in England specially devoted to military and naval surgery. Some eleven years later a second edition appeared, and this is its title—"Viaticum, being the Pathway to the Surgeon's Chest, containing chirurgical instructions for the younger sort of surgeons imployed in the service of his Majestie or for the Common-Wealth upon any occasion whatsoever intended for the better curing of wounds made by Gunshot," by John Woodall. A perusal of the "Viaticum" shows that Woodall was a very practical surgeon and an eminently religious man, and the way in which he mixes up pills and piety is sometimes very diverting. After some excellent general advice to the surgeon's mate, including a warning against "being given and dedicated to the Pot and Tobacco-pipe in an unreasonable measure," he enumerates the instruments for the surgeon's chest, including among others Catlings, Rasours, Trapans, Trafine, Lavatories, Cauterising Irons, Storks' bills, Ravens' bills, Crowes' bills, Terebellum, Probes or flamules, Glister Sirings and (what would have utterly damned his book in the present day) "one bundle of small German instruments." Then comes a list of medicines under the heading Unguentum, Aqua, Sol, Oleum, Chemicall Oyles, Syrups, Conserva, Electuariæ, and so on, winding up with a list of the Simples, and of the Herbs and Roots most fit to be carried. A long and careful description of the uses of the instruments and drugs follows, and then come chapters on wounds, apostumes, fractures, dislocations, amputation, scurvy, the plague, gangrene, and other topics. He observes that the cauterizing irons had gone somewhat out of fashion, and he did not use them much himself "because of the feare they put the Patient into and for speech of people who are ready to scandalise an Artist upon each light occasion." In amputation, moreover, they are "now wholly forborne for reasons aforesaid, and for that a more pleasant course is known better for the patient and the Artist by making a ligature upon the veine, wound or artery, which is the binding of each end thereof, being first caught and holden with some fit instrument, and tied with a sure and strong thread."

Woodall advances the cure of wounds a distinct step, once more putting us under an obligation to the soldier-surgeon. This he does by sharply attacking all through his works the inordinate and meddlesome use of strong caustics. He says that he had seen men lamed by the needless use of caustic medicines, even in slight wounds, to which if an old wife had only applied her one salve for all sores, no such thing had happened. "They will not see a wound incarne and red and good flesh to grow, but straight they slander it of pride, and call it proud flesh, like their owne: and then must at the fairest Precipitate or Vitriale burnt goe to work, yea though the Patient be lame for it, or at the least the griefe put back again."

Richard Wiseman.—I wish I had time to give you a proper account of the adventurous life of Richard Wiseman, who has been termed the father of English surgery, and that not without reason. Born in 1620, dying in 1676, he lived in the time of Charles the First, of the commonwealth, and of Charles the Second. He was a naval surgeon to begin with, serving in the early part of his life in the Dutch navy. Being, however, a devoted Royalist, he served with the armies of Charles the First, and after his death went into exile with his son in France. He was present at the battle of Worcester, where he was taken prisoner, and afterward confined in Lambeth House for a while. During the commonwealth he was naturally under a cloud, and even went off for three years to serve in the Spanish navy. At the restoration the King did not forget his old surgeon, who had done and suffered so much in his service, but appointed him his surgeon-in-ordinary, and afterward sergeant-surgeon. The first edition of his work, printed in 1672, is quite a small book, and is entitled "A Treatise of Wounds," but it afterwards expanded into a very large volume.

Nothing reveals a man like his own words, and so in trying to give you an idea of these old worthies I have let them tell their own stories. Wiseman believed in the need for giving stimulants to a man who was in the habit of taking them, if that man was in a dire strait. After describing the parlous case of a certain patient, it seems that the "man swooned and complained that he could not live without wine. I complied with his desire; he drank again as he pleased, his sickness went off, his wound digested, and he cured. This I have often seen in some of our Dunkirkers at sea, who drank extraordinarily, and were full of drink in our sea fights. I could scarce ever cure them without allowing them wine, and thereby their spirits were kept up, and I had the liberty to bleed them as I thought fit." From this it is clear that the old saying about Dutch courage has a distinct origin in fact. But if the unhappy Batavians were liable to be bled at once by the lance of the enemy and the lancet of the surgeon, one can hardly wonder at their taking something to keep their spirits up.

When speaking of gunshot wounds, he insists upon the bullet being searched for and extracted at once. "The part is at first dressing, with what diligence you can, to be cleared of all such Foreign Bodies as have made violent Intrusion into it, while the patient is warm with the heat of Battel, and the wound fresh and very little altered by either Air or Accidents, so that less pain must necessarily follow upon the extraction. In the Armada Naval de Dunquerque, where we Chi-

rurgeons were oft employed in this Service, we after every fight went together visiting one another's wounded men. Amongst us it was thought a great shame if any of this work of Extraction was there to be done. It hath been the cause of the death of many a brave Souldier, and every Battel produces instances of it, to the discredit of our profession." This is good surgery and straight talk. I think it must have been a fine spectacle to have seen these rough old surgeons, with their limited knowledge and their miserable means of treatment, walking round to see each other's patients and learning how best to mend their mistakes.

He has a chapter entirely devoted to a great case of a fracture made by a splinter. The patient had his arm badly smashed above the elbow, and ought to have had it amputated; but a sudden cry of fire stopped this. "I hastily clapt a dressing upon his wound and rouled it up, leaving his arm in his other hand to support it, and endeavoured to get up out of the hold as the others did, I verily believing I should never dress him or any of them more. But our men bravely quitted themselves of the Fire-ship by cutting the Sprizil Tackle off with their Hatchets (which they wore during fight sticking in their Shashes); we were freed of the fire, and by our hoisting up the top sails got free of our Enemy. Now, I was at a loss what to do with this man, who lay not far off complaining of his arm. I would have cut off his arm presently with a Razor (the Bone being shattered there needed no Saw); but this man would not suffer me to dress his arm; he cryed 'it was already drest.' The Fight over, we got into the next Port; I caused presently the Mariner's Bed to be set up (which was four pieces of wood nailed together and corded, and a Bear's skin laid upon it); this was fastened between two Guns to the Carriages." Wiseman then set hard to work to save this unfortunate mariner's arm; but "when it came to my turn to be visited by my brother Chirurgeons of our Squadron, they did not dislike the wound nor my way of dressing (for we, being used to see one another's Patients, had all much one way of dressing); but they laught at the excuse I made for not cutting of his arm, and doubted I should yet be forced to do it. But at the end of two months there was in this Patient a strong callus, filling up the void place of the lost Bone at least two inches, with little or no shortening of the arm." Well done, Wiseman!

Baron Larrey.—Up till the time of the French Revolution it is clear that military surgeons were not men of much importance, and probably had very little influence, if any, in the conduct of campaigns. But in the latter part of the last century war was made on a scale which was never known before, and was made also with a rapidity and a precision quite unprecedented. Moreover, the science and art of surgery had been rescued from quackery, and surgeons in actual practice were able to be of great and real service to the wounded. As a result of the vast masses of men that were hurled against each other, the number of wounded after a big battle amounted to thousands, and civilization had so far advanced that it was imperative that immediate help should be given to them. So that about this time the military surgeon really became an important officer in warfare, and began to have his rank and pay well defined, and his merits (up to a certain point) recognized.

In 1776, near the Pyrenees, was born Jean Dominique Larrey, the chirurgien-en-chef de la grande armée, the friend and body surgeon of Napoleon, the greatest military surgeon that ever lived. He studied at the medical school of Toulouse, and in 1792 joined the headquarters of the Republican army of the Rhine under Custine. Now, the ambulances of these days were obliged to remain about a league from the army, and the wounded were picked up only after the fighting was done. General Custine was a man who moved his troops very rapidly, which made matters worse for the wounded. This greatly affected Larrey, who set to work and devised a new ambulance hung on springs, and combining great strength with lightness. Such carriages were termed *ambulances volantes*. They could keep up with the advanced guard of the army with the speed of flying artillery, and they carried off the wounded almost as they fell. Larrey had early perceived the enormous advantage a wounded man got by having his fracture set or his bleeding stopped as rapidly as possible, and by then getting a roof over his head before night set in. General Beauharnais, in a dispatch to the Convention, made special mention of "Surgeon-Major Larrey and his comrades with flying ambulances, whose indefatigable care in the healing of the wounded has diminished those afflicting results to humanity which have generally been inseparable from days of victory, and has essentially served the cause of humanity itself in preserving the brave defenders of our country." The staff of a flying ambulance was about three hundred and forty in number. For each division there were four heavy carriages and twelve light ones. Some had two and others four wheels, and they were furnished with mattresses. In Napoleon's Italian campaigns they came greatly to the fore, and the great man displayed a lively interest in them, reviewing them and causing them to manœuvre before him just as if they were on a battlefield. After one of these inspections he said to Larrey: "Your work is one of the most happy conceptions of our age. It will suffice for your reputation."

When Napoleon undertook his Egyptian campaign Larrey proceeded to Toulon to organize the medical staff. So readily did professional men respond to the call made by him that he soon was able to reckon on eight hundred well-qualified surgeons, of whom many had served in the army of Italy, and these were in addition to the medical officers actually attached to regiments. This, I think, shows the value that the king of commanders set upon the health of his troops, and the trouble and expense which he was prepared to face in order to maintain it—a great contrast to the miserable way of dealing with this subject which has too long been the fashion with our military rulers. Not long after the landing at Alexandria a certain General Figuières was severely wounded. By able treatment he recovered, and in gratitude for the preservation of his life he asked Napoleon to accept a valuable Damascus sword. "Yes," said the latter, "I accept it in order to make a present of it to the surgeon-in-chief, by whose exertions your life has been spared." Upon the sword were engraved the words "Aboukir" and "Larrey," and the surgeon had it till the fatal day of Waterloo, when the Prussians robbed him of it. Some months after the occupation of Egypt a terrible revolt took place in Cairo by fanatical Turks. Utterly regardless of anything except how to get at Frenchmen to murder them, they attacked the hospital, which was crowded with sick and wounded soldiers, but the doctors valiantly defended their patients, and two staff-surgeons, Roussel and Monjin, were killed, while Larrey nearly shared the same fate.

At one period there was a total dearth of meat, and Larrey had nothing wherewith to make even a drop of bouillon for his patients. He ordered camels' meat to be used for this purpose, and, when that fell short, he used up the horses. Years afterward, in the second campaign against Austria, the imperial guard and several other corps were crowded together in the island of Lobau in the midst of the Danube, which Napleon was endeavoring to cross. The days were roasting and the nights icy cold, and provisions became so sarce that Larrey's patients were in danger of starvation. Without more ado he impounded cer-

tain officers' horses and had them slaughtered and employed as food. As there was a lack of kettles, he employed the cuirasses of those who had been killed, and made his horse-flesh soup and stews in them. Certain generals made bitter complaint to the emperor of Larrey's proceedings, who summoned the surgeon-in-chief, and in the presence of his staff demanded an explanation with a severe expression of countenance. "What," he said, "have you on your own responsibility disposed of the horses of the officers in order to give soup to your wounded?" "Yes," answered Larrey. He added no more, but soon afterward he heard of his promotion to the rank of baron of the empire.

One of the most appalling retreats, next to that from Moscow, was Napoleon's retreat from the invincible walls of St. Jean d'Acre through Jaffa. There is no doubt that at that place considerable numbers of patients sick of the plague were quietly put out of their misery by opium. Alison says sixty; Sir Robert Wilson says five hundred and eighty. The retreat had to go on, the Turks were only an hour's march behind, and nothing but a cruel death awaited these unfortunates, so that whether this were a justifiable deed or not may well give ground for argument. But, as Alison says: "History must record with admiration the answer of the French chief of the medical staff when the proposal was made by Napoleon to him: 'My vocation is to prolong life, and not to extinguish it.'"

In those days means of transport were so inferior, and the necessity for removing hopelessly damaged limbs as soon as possible after the injury so imperative, that amputations were performed on the field of battle, while it was still raging, and amid showers of bullets. During the battle produced by the landing of the English in Aboukir Bay, General Silly had his knee crushed by a bullet. Larrey saw that unless the leg were promptly amputated the case would prove fatal, and, the general giving his consent, the operation was performed in the space of three minutes under the enemy's fire. Just then the English cavalry came upon them. "I had scarcely time," said Larrey, "to place the wounded officer on my shoulders and to carry him rapidly away toward our army, which was in full retreat. I spied a series of ditches, some of them hedged with caper bushes, across which I passed, while the enemy, owing to the ground being so cut up, had to go by a more circuitous route. Thus I had the happiness to reach the rear guard of our army before this corps of dragoons. At length I arrived at Alexandria with this honorably wounded officer, where I completed his cure." We must all agree that these were a pair of heroes.

As may be imagined, the awful retreat from Moscow called into play all Larrey's resources, and many an interesting story could be told of his efforts. Think of the awful battle of the Borodino, where under Larrey's own direction two hundred amputations were performed, where there were neither couches nor blankets nor covering of any kind, and where the food consisted of horseflesh, cabbage stalks, and a few potatoes. Think of cold so intense that the instruments requisite for the operations too often tumbled from the powerless hands of the French surgeons. Think of the savage Cossacks, hovering about all the while, and waiting their chance to kill the surgeon and the wounded men equally with the combatant. Then came the passage of the Beresina. Take an incident of it. Among the wounded was General Zayonchek, who was over sixty years of age. His knee was crushed, and without amputation the saving of his life was impossible. It was performed under the enemy's fire, and amid thick-falling snow. There was no shelter except a cloak, which two officers held over him while the operation was being performed; but the surgeons did their work with such coolness and dexterity that the old general survived, and died fourteen years afterward viceroy of Poland. Larrey succeeded in getting over the Beresina with the imperial guard, but discovered that the requisites for the sick and wounded had been left on the other side. At once he recrossed the river, only to find himself in the midst of a furious struggling crowd. He was on the point of being crushed to death when providentially the soldiers recognized him. No sooner did they do so than they carried him across the river in their arms, with the cry, "Let us save him who saved us!" and forgot their own safety in their desire to preserve the man whose tender kindness they had so often experienced.

Following his adored master through victory and defeat, Larrey at last stood at night on the field of Waterloo, alone except for some medical officers and the wounded who lay groaning around them. Down upon them came a squadron of Prussian lancers. Expecting no quarter, he fired his pistols at them and galloped away. They shot his horse and sabred him as he lay on the ground. Leaving him apparently dead, they went off. But he recovered his senses, and tried to crawl by crossroads into France. Again he was seized by another detachment of Prussian cavalry. They robbed him promptly of all he possessed, and took him before a superior officer, who ordered him to be shot. What a reward from a soldier to one whose life had been passed in succoring soldiers! About a quarter of an hour before the sentence was to be carried out, a surgeon-major recognized Larrey. He had attended with deep interest a course of lectures which Larrey had delivered in Berlin six years previously. The prisoner was brought before Bulow, and finally presented to Blücher, whose son in the Austrian campaign had been badly wounded and captured by the French, and who owed his life to Larrey's exertions.

Larrey's honorable and glorious life terminated in 1842. Napoleon, when he made his will at St. Helena, wrote in it: "I bequeath to the surgeon-in-chief of the French army, Larrey, 100,000 francs. He is the most virtuous man I have ever known." From Napoleon's lips the words of free, spontaneous, ungrudging praise such as this rarely fell.

Pestilence More Deadly than the Sword.—In the middle of the last century, while surgery had distinctly improved, the gross neglect of the government and the pig-headed obstinacy of the generals were such that our unfortunate soldiers and sailors were hardly any better off than they were in the days of Paré. It has been maintained that Smollett, in the appalling picture of naval life as witnessed in the miserable expedition to Carthagena which he drew in "Roderick Random," and which is known to have been the record of his own experience as surgeon's mate, grossly exaggerated the evils thereof. I do not believe this. Look at the awful and unsuccessful expedition to Porto Bello in 1726, when nearly the whole of the crews of the ships were destroyed by fever three times over; where 2 admirals, 10 captains, 50 lieutenants, and about 3,000 to 4,000 inferior officers and men perished without striking a blow. Look at the taking of Havana in 1762. The Earl of Albemarle took with him in the fleet 11,000 soldiers. Between June and the middle of October, when Cuba was ours, we had lost 560 men by wounds, and 4,708 by sickness. At the end of the seven years' war a statement was drawn up in the "Annual Register" for 1763, from which it appeared that in all the naval battles of that war there were but 1,512 sailors and marines killed, while 133,738 had died of disease or were "missing." Look even at the end of last century, and consider the wretched and disgraceful Walcheren campaign. Never did our poor soldiers fight with more gallantry than in that cam-

paign, only to perish beside Dutch ditches and canals from fever and ague and dysentery.

Military Courage.—As we have just seen, Baron Larrey's whole life shows that, while absolutely devoted to the work of his profession, he displayed a cool courage on the field of battle not less heroic than the more dazzling deeds of his fellow combatant officers. Not less does it mark the military surgeon of the present day. Have you ever heard of Surgeon Thomson, who, during the Crimean war, when the army marched off after the battle of the Alma, volunteered with his servant, John McGrath, to remain behind on the open field with five hundred terribly wounded Russians, and passed three awful days and nights—these two Englishmen alone—among foreign foes, some dead, some dying, and none able to raise a hand to help themselves? Have you ever heard of Assistant Surgeon Wolseley, of the twentieth regiment, who, at the battle of Inkerman, had quietly established his field hospital in that awful place, the Sandbag Battery? When the one hundred and fifty men, who were all that remained of its defenders, were forced to desert it, about one hundred of them fell back in one direction, and in that they found, at thirty paces from them, a Russian battalion blocking their path. There was not a combatant officer left, so the assistant surgeon took command. He had not even a sword with him, but, laying hold of a firelock with a fixed bayonet on it, he spoke a few words to the men within range of his voice, and told them that what they now had to fight for was not victory but life. Then he gave them the word of command: "Fix bayonets, charge, and keep up the hill." The soldiers answered him with a burst of hurrahs, sprang forward to the charge, and the next instant were tearing through the thickest of the Russians. One-half of these reached the other side alive. Have you ever hard of Surgeon Landon, who was shot through the spine while attending to the wounded on Majuba Hill? His legs were paralyzed, but he caused himself to be propped up, and continued his merciful work till his strength ebbed away. When unable for more he quietly said: "I am dying; do what you can for the wounded." Have you ever heard of Surgeon-Captain Whitchurch, who gained the Victor a Cross at the beleaguering of Chitral for the most determined courage in endeavoring to save the life of Major Baird? Yes, you have, for last year at Carlisle you gave him the gold medal of the association, the highest honor which our association can give to its members. There died the other day a certain Surgeon-General Reade, C.B., V.C. During the siege of Delhi, while attending to the wounded at the end of one of the streets of the city, a party of rebels advanced from the direction of the bank, and, having established themselves in the houses in the street, commenced firing from the roofs. The wounded were thus in very great danger, and would have fallen into the hands of the enemy had not Surgeon Reade drawn his sword and, calling upon a few soldiers who were near to follow, succeeded under a very heavy fire in dislodging the rebels from their position. Surgeon Reade's party consisted of about ten in all, of whom two were killed and five or six wounded. Ladies and gentlemen, Surgeon Reade was a Canadian, and the son of a colonel of the Canadian militia. Of the one hundred and eighteen wearers of the Victoria cross fourteen are surgeons, nearly twelve per cent. of the whole number. They stand in the proportion of 9.5 per cent. of all the officers of the army, so at all events they have contributed not less than their fair share of the deeds of valor which alone can win that glorious distinction.

The Army Medical Service To-day.—Ladies and Gentlemen: I have diverged from the beaten track common to the givers of addresses such as this to tell you what splendid men have been the military and naval surgeons of old, who not merely did their duty nobly and courageously as such, but who have in their day enormously contributed to the advance of the art of surgery. I have done it with a purpose; with the hope of attracting more strongly than ever the sympathy and help of this great association to their military brethren in a critical juncture of their history. To-day Her Majesty's government cannot induce candidates to come forward for the medical service of the Queen's army. And why? Because it has persistently treated the army medical department meanly and shabbily. To-day the government of India can secure the services of the pick of our newly fledged doctors for its army. And why? Because it has always treated the Indian medical service liberally and generously. I am not going to enter into the reasons for this; I desire merely to emphasize one point, namely, that money is not at the bottom of this difficulty. The soldier surgeons of to-day are the same men now that they were in the days of William Clowes, who winds up his book, as I shall my address, with these verses:

> "When valiant Mars, with brave and warlike band,
> In foughten field with sword and shield doth stand,
> May there be mist a surgeon that is good,
> To salve your wounds and eke to stay your bloud.
>
> "To cure you sure he will have watchful eie,
> And with such wights he means to live and die,
> So that againe you must augment his store,
> And having this he will request no more."

THE PROGRESS AND RESULTS OF PATHOLOGICAL WORK.[1]

BY W. WATSON CHEYNE, M.B., F.R.C.S., F.R.S.,
LONDON, ENGLAND,
[illegible]

GENTLEMEN: On such an occasion as this one is naturally tempted to look back on the history of pathology during the last sixty years, but I hope that you will not expect me to follow the fashion in this respect. To trace the history of pathology during the last sixty years would be to follow the science practically from its commencement and go back to a state of matters which it is almost impossible for us now to realize. Even going back to the time when I was first introduced to the study of pathology, some twenty-five years ago, the changes which have taken place are enormous. At that time the lectures on pathology consisted practically entirely of morbid anatomy—long descriptions, for the most part very accurate and not materially different from those of the present day, were given of the naked-eye appearances of the diseased parts, but as to how or why these changes were brought about hardly any reference was made. Indeed, very little was known, and when an explanation was attempted it was generally of a mechanical or physical character. At the present time, while, of course, the changes which take place in disease must be known, the study of pathology is especially directed to the discovery of the mode in which these changes occur and the reasons why they appear. To-day it is the etiological side of pathology, so to speak, which occupies our attention, and deservedly so, for, so far as practical results in the treatment of disease are concerned, the knowledge of the changes produced is of comparatively minor importance as compared with that of the reason why they are set up and how they take place. The more accurately we can trace the etiological factors in disease and the subsequent course of events, the more likely are we to arrive at a rational method of treatment.

[1] An address delivered at the opening of the section of pathology, at the annual meeting of the British Medical Association, at Montreal, September 1, 1897.

The most striking and important advance has been the growth of the great science of bacteriology, a science which has not only led to most important practical results, but has also thrown a flood of light on the processes which go on in the body as a whole, and has stimulated research in other directions not immediately associated with it. Twenty-five years ago bacteriology as a science was non-existent. So far as I remember bacteria were not even alluded to in our course of pathology, and it was only from Lord Lister that we heard the real facts so far as they were known, or gained any idea of the importance of their study; but even at that time, although his methods of treatment were already yielding brilliant results and saving many lives, and although he had deduced from clinical facts many points in the life history of bacteria and their relations to the living body, which were only confirmed by experiment subsequently, still the number of actual proved facts was extremely few.

It is difficult for those who have taken up the subject of bacteriology only comparatively recently to realize the absolute blank which it presented even twenty years ago. When I became house surgeon to Lord Lister in 1876 objections of all kinds were urged against the theory on which Listerism was based, some denying the existence of bacteria at all, others maintaining the theory of spontaneous generation; some asserting that organisms were always present in the healthy tissues, others denying that they had anything to do with disease, or that the success of the antiseptic principle depended in any way on the exclusion of micro-organisms from wounds. It was these objections which led me to take up bacteriology, for it seemed to me of great importance to ascertain whether or not, as the result of antiseptic treatment, organisms were absent from the discharges from the wounds. Although at the present time such an investigation would be one of the simplest, yet when I came to carry it out I was met with the greatest difficulties. Practically nothing of the kind had been done before, and all the means of investigation had to be devised. Methods of staining bacteria had not been introduced, we had no oil-immersion lenses, and I very soon found that by looking at discharges from wounds containing leucocytes, granular matter, and *débris* with dry or water immersion lenses, and without substage condensers, no satisfactory result could be arrived at. Hence I came to the conclusion that attempts must be made to see whether organisms grew in suitable fluids inoculated from the discharges. Here again everything had to be devised. A suitable pabulum, methods of sterilization, of inoculation, and of incubation had to be worked out. A large amount of time was spent in getting over the preliminary difficulties, and after a satisfactory method had been found much labor had to be devoted to preliminary questions, such as spontaneous generation, morphological characters of bacteria, their presence or absence in the living body, conditions of growth, and so on.

A great advance which followed soon afterward was the remarkable research by Lord Lister on the bacterium lactis, in which he devised a method of separating bacteria by fractional cultivation, which resulted in the separation of the bacterium which causes lactic fermentation from other organisms. By this research, apart from the method, a great step was gained in the proof of the specificity of a particular bacterium, both as regards morphological characters and chemical action.

Then came Koch's work on infective diseases of wounds, and the publication of his methods of staining and examining bacteria and of cultivating them on solid media, and this work is at the foundation of all modern bacteriological research. From this period the investigations have branched off in two directions. In the first place, almost all the infective diseases have been investigated for parasitic organisms, and in a large number the causal agents have been identified. And, in the second place, researches have been carried on in the direction of tracing out the life history and functional activity of bacteria, and of ascertaining what occurs in the body when organisms or their products are introduced.

From the latter point of view we come to another great landmark in the study of bacteriology, namely, Metchnikoff's work on phagocytosis, a theory which is not only very fascinating in itself, but which has proved a most suggestive working hypothesis leading to many of the researches which have given bacteriology its present position. What a remarkable series of views have been opened up in this direction: questions of the relation of the cells of the body to the parasite, the differentiation of cells, alterations in serum, chemiotaxis, the development of the protective agencies and of antibacteric substances, antitoxins, immunity, and so forth. And yet we are clearly only on the threshold: the very simplicity of many of the explanations is, to my mind, sufficient to show that they are incomplete, for the workings of the living body are far too intricate to be summed up in a simple formula.

In spite, however, of all that has been done, many problems still remain unsolved. In the case of tuberculosis, why is it that in one part of the body we have a slow-growing lupus disease, and in another part, perhaps, of the same body a rapidly developing tuberculosis? None of the explanations usually given, such as differences in the structure or resisting power of the tissues affected or of the individual, differences in the virulence or activity of the organism, etc., seems to furnish sufficient explanation. And the same problem is apparently presented with regard to the bacilli of diphtheria, in that we may have in one case a true diphtheria, in another a membranous rhinitis, while in the third, although the bacilli are present in the throat, the individual may be apparently healthy.

Another very remarkable problem is presented by the results which follow free incisions into tuberculous tissue. An incision is made into the abdominal cavity, masses of tuberculous tissue and tubercle are found scattered over the peritoneum; nothing whatever is done, the wound is stitched up, and yet in many cases the patient, who up to that time has been going steadily down hill, begins to pick up, and the disease may come entirely to a standstill. This phenomenon is not limited to peritoneal tuberculosis. When I was a student the tuberculous nature of what are now recognized as tuberculous diseases of bones and joints was then only suspected, and was not generally accepted by the medical profession. At that time Lord Lister, under the impression that these diseases were of a simple inflammatory nature, and having observed the improvement which often followed free incisions into chronically inflamed tissues, began as an ordinary line of practice to make free incisions through the thickened synovial membrane of tuberculous joints with the view of relieving tension, which he looked on as the chief cause of the continuance of the trouble. Nothing else was done, the joint was not even washed out, nothing was taken away, and yet in a considerable number of cases so treated improvement began from the time that the incisions were made, the patients lost their pain, the wounds gradually healed up, and the disease subsided. Even in cases in which the results were not so satisfactory it could as a rule be noted that, although the swelling continued in other parts of the joint, and although the disease began again after a few weeks as vigorously as before, yet for a time at least the thickening disappeared in the neighborhood of the scars, showing that there at any

rate temporary benefit had occurred. What possible explanation can we give of such a result? The older surgeons used to speak of "setting up a healthy action in the part," and were quite satisfied with that statement. Such a view is too vague for us nowadays, but may there not be here a possible working hypothesis which if followed out might throw light on this matter? May not the occurrence of healing processes at one part influence in some way or other morbid processes in the vicinity?

Again, what is the meaning of a chronic abscess? How is it that the tubercle bacilli at one time produce a quantity of tuberculous tissue, at another a cheesy mass, and at another a chronic abscess? I do not for one moment accept the view that we have in the latter case to do with a mixed infection, and that the pyogenic organisms have died out before the abscess was opened.

In connection with the pyogenic organisms also we have many problems. How is it, for example, that after an abscess is opened antiseptically suppuration at once ceases? If instead of opening the abscess antiseptically a poultice be applied, suppuration goes on and may be very profuse. But if it be opened at a time when there is free fluctuation and when it is beginning to point, and if the necessary antiseptic precautions be taken and proper drainage provided no more pus forms, and yet when the abscess is opened it is found to contain living pyogenic organisms. We can easily understand that the subsidence of the fever and general disturbance is due to diminished absorption of toxic products. But why do not these living pyogenic organisms keep up the suppuration? and why is it that after two or three days one may fail to obtain any cultivations from the serum which escapes from the wound? If the inflamed part be opened up antiseptically, however, at an early period, just when pus is beginning to form, there is not always the same complete absence of suppuration, although it seldom goes on to any considerable extent.

Again, an operation wound becomes septic and one naturally opens it up freely and establishes drainage: but here suppuration does not cease at once in the same typical manner as in the case of an abscess which has existed for some days. The old surgeons used to speak of an abscess being "ripe," and they allowed it to remain unopened for some days till it was pointing. They found that if they opened a deep abscess early, suppuration went on and was apt to extend. No doubt a variety of causes led to this dictum: they did not provide proper drainage; they introduced other and more vigorous organisms at the time of operation and afterward, etc.; but do not the facts seem to indicate that, as regards the cessation of suppuration, there is some ground for this idea of ripeness? Is it possible that when the abscess has attained a considerable size and the tension of the pus in it is great the sudden release of the pent-up fluid may lead to such a pouring out of serum containing antitoxic substances as absolutely to destroy the organisms present, while, the case being treated antiseptically, no fresh organisms can come in to take their place? And yet I can hardly think that that is the whole explanation.

Although it is in the department of bacteriology that the most striking advance has been made, great progress has also gone on in pathology generally, in a considerable number of cases no doubt stimulated by the results of bacteriological research, and more especially by Metchnikoff's work. The subject of inflammation has had much attention paid to it as the result of these studies, although I cannot say that to my mind it has been made any clearer. The tendency now appears to be to regard inflammation as the natural effort at repair after injury. At one time this was the view held by surgeons, and the doctrine was that inflammation was essential to healing, and in the description of healing by first intention it was stated that a red blush occurred around the wound, not so severe, however, as where suppuration takes place, and that without this red blush the edges did not adhere. When antiseptic treatment was introduced it became evident that no inflammatory blush or other sign of inflammation was necessary for healing by first intention; in fact, it was found that wounds healed best when no visible sign of inflammation was present. I have, therefore, always taught that inflammation and healing are two different and, indeed, to some extent antagonistic processes, and that although in every wound the tissues in resenting the injury show the early stage of inflammation, yet if no organisms be admitted the inflammatory phenomena soon pass off, and where there is destruction of tissue a second process, namely, that of repair, begins. As I have said, in recent writings the tendency appears to be to look on inflammation and healing as parts of the same process; but in spite of the very able arguments adduced in favor of this view I am still unconvinced. I still look on inflammation as the mechanism which gets rid of noxious agents or neutralizes their effects, and on the healing process as that which repairs defects, whether they are caused by injury and associated with inflammation or not. In fact, inflammation must be followed by repair if recovery is to take place, but repair need not be preceded by inflammation. The difficulty arises from the close association of the two processes, both of which have to do with the growth of cells, and from the fact that repair follows as soon as the inflammation begins to subside. Hence under the microscope, except in cases of acute suppurative inflammation, one sees the two processes at work side by side, and it is not a matter of surprise that they should be confounded. As a matter of fact, the more the cellular processes are investigated the more it becomes evident that there is a marked differentiation of cells as regards function.

When Cohnheim first published his observations on the emigration of corpuscles it was thought by many that the leucocyte was everything and did everything, but it was soon evident that other cells of different origin must be taken into consideration. When Metchnikoff's theory of phagocytosis first came out, some of those who adopted it assumed that all wandering cells were phagocytes; but here, again, further investigation has shown that cells differ greatly as regards their phagocytic action. I think that a good deal of the confusion of these processes arises from the fact that expressions involving a teleological argument are becoming very common, more especially with regard to the protective arrangements of the body. On the idea of an acting intelligence on the part of the cells, the two processes would naturally go together; but, looked on as the simple effect of an injury, they should, I believe, be regarded as independent, and the less and the shorter the inflammation the better and quicker the healing process.

A very remarkable thing in connection with these advances, especially in experimental pathology, is the enormous direct practical benefit which has already resulted to the human race; and it is sufficient answer to the antivivisectionists who oppose the use of intelligence and observation and experiment, to point to the saving of human life and the relief of suffering which has taken place in the last few years. Since Pasteur's experiments on spontaneous generation were published, only thirty-six years have elapsed, and during that time remarkable results have been attained in treatment as the result of experimental pathology.

Scientific effort to arrive at the truth as regards the workings of nature are necessarily slow, and must be carried on without any regard to possible ultimate

practical results. When the earlier investigators studied the phenomena of electrical action, I doubt if it ever occurred to them that the result of their study would be of any practical value; certainly they could have had no idea of the revolution which the study of electricity would effect in the history of the world. When Pasteur resolved to test the theory of spontaneous generation, it did not seem likely to lead to any beneficial result; indeed, his friends tried to dissuade him from entering into what was apparently a useless investigation, and yet what numbers of human lives have been saved as the result of that work, and what incalculable benefit has accrued! It is greatly the fashion with the opponents of experimental research to demand a single instance in which an experiment has led to the discovery of a means of cure; but in no department of science has a single experiment of itself alone led to the practical result; the final observation which led to the practical result has been built up on numerous and laborious preliminary investigations and observations. And similarly, in regard to the cure or prevention of disease, the final trials on man have been led up to by numerous preceding observations and experiments. If these deluded people had their way, the result would be that experiments would be limited to man, and every one to whom a new idea occurred would apply it without any previous investigation—surely an appalling prospect, whether for physician or patient.

The practical results already obtained affect diagnosis, prophylaxis, and treatment. The diagnosis of many parasitic diseases has now been rendered certain and easy by searching for the causal organism, and I need only instance such diseases as diphtheria, tuberculosis, malaria, anthrax, gonorrhœa, etc. And it is not only by the discovery of the parasite that diagnosis is assisted, but also by other effects of the organism, such as the sort of changes set up in the tissue, the reaction to products of the organism, for instance tuberculin and mallein, etc., and we shall hear a good deal about one of these diagnostic advances in the course of the meeting, namely, the action of the serum of typhoid patients on motile typhoid bacilli. If no other practical advance had resulted from bacteriological work, the possibility of establishing a definite diagnosis in obscure cases is surely a gain of the utmost importance, for it enables a rational prophylaxis and treatment to be instituted.

The greatest of all the advances, because so wide-reaching, has been in the prophylaxis of disease, especially in the prevention of septic disease after operations, as brought about by the discoveries of Lord Lister. By these discoveries the occurrence of sepsis in wounds made through unbroken skin is prevented, and the chances of general sepsis in septic wounds are much diminished, and numerous lives are saved, not only in this way, but also by the fact that the Listerian treatment permits the performance of many life-saving operations which could not otherwise be attempted. In other cases also, prophylaxis is of great value, as in diphtheria, and in Pasteur's treatment of rabies, which may properly be grouped as a prophylactic rather than a curative treatment.

Lastly, I may refer to advances in the cure of disease. In the case of diphtheria there can be no question that the antitoxin is a most potent curative agent, and that, used in the early stages, it is almost certain to cut short the disease. As regards tetanus, the evidence in the case of animals is absolutely convincing, but in patients suffering from the disease the effect is not certain, probably because we have to do with an acute illness, which runs its course before the serum has had time to act. The same may also be the case with the antistreptococcic serum, although I have great doubts of its value as a curative agent. In other instances, such as plague and snakebite, we may apparently look forward to a cure; while researches are being carried on with regard to pneumonia which may lead to valuable results; nor must I forget to mention Pasteur's system of inoculating cattle against anthrax. What are we to say about the new tuberculin? We all know how careful an observer Koch is, and the fact that he looks on it as a valuable remedy is to my mind sufficient to make it necessary to give it a careful and hopeful trial. I must say that I have always been favorably inclined to the old tuberculin, and have regarded it in relation to phthisis like iodide of potassium in relation to syphilis, and, had I been a physician, I do not think I should have abandoned it in the hurried manner in which it was thrown aside.

But it is not only in the direction of bacteriology that advantage has resulted from pathological research. Look at the advances in treatment from the use of organic fluids. As the result of observations on man and researches on animals as to the effects of excision of the thyroid gland attempts were made to transplant the healthy thyroid gland into animals and patients in whom it was absent, and following these attempts the use of thyroid extract has ultimately come to be a recognized method of treatment. There is, perhaps, nothing more striking in medical treatment than the rapid and remarkable improvement in cases of myxœdema from the use of thyroid extract.

I might enumerate many other instances of direct benefit from pathological research, such as the advances in the treatment of tuberculous diseases of bones and joints as the result of better knowledge of the nature and distribution of the disease, the treatment of appendicitis, and the investigations on peritonitis and diseases of the appendix, the more complete operations for cancer following fuller study of the mode of spread of the disease, and so on; but I have said enough to show the great importance and value of pathological research. Such results must encourage us to go on working with all our might and without ceasing, bearing in mind that many are suffering and dying every day who might be saved if only we had just a little more knowledge of the workings of the body and the processes of disease.

But while pathologists are thus working out problems which affect the general well-being of mankind, and the solution of which can be of no personal gain to themselves, is it too much to ask mankind to furnish the means for such research? The English are looked on as a thoroughly practical people, and yet it is a very remarkable thing that England is almost the only country which does not realize the importance of scientific research, and the result is that in England, with very few exceptions, men who might otherwise have thrown much light on these matters are compelled to turn their attention to practice in order to make a living. Unless work of this kind is done how can we hope to advance with any rapidity in the treatment and cure of disease? The surgeon or physician must wait till the information of which he is urgently in need has been acquired for him by the pathologist. Such apathy can surely be the result only of ignorance. A rich man affected with an obscure or incurable malady cannot understand how it is that he fails to obtain the definite opinion or the relief which he so earnestly desires, and for which he is prepared to pay any price. Surely if he understood the meaning and importance of pathological research, and that the practising physician can apply and carry out only what is taught by the pathologist, he would bestir himself to aid research in order to gather information which might be of much use to him and to others.

Torpid Ulcers, even when painful and due to varicose veins, may be made to cicatrize comfortably if dusted daily with antipyrin.—SCHREIBER.

Progress of Medical Science.

Bilateral Optic Neuritis Complicating Enteric Fever.—Braine-Hartnell (*British Medical Journal*, May 29, 1897) has reported the case of a boy, eleven years old, of weak intellectual development, who "ailed" for a few days, without presenting any definite symptoms. On the third day the temperature was 103.4° F., and his bowels were moved five times. For the next four days the bowels were moved twice daily. The child was restless and noisy, and could with difficulty be kept in bed. Photophobia and signs of cerebral irritation developed. The face was pale, the pupils were equal, the tongue was dry, and sordes formed on the lips. The bowels were not loose from the seventh day until death took place, upon the eighteenth day of the illness, but formed stools were constantly passed. The abdomen was if anything somewhat retracted. There were no spots; the spleen could not be felt, nor could an enlarged area of percussion dulness be made out. The temperature fell on the tenth day to normal, but rose again on the fifteenth, and on the eighteenth day, just before death, it reached 105.2° F. The pulse rate varied from 120 to 160. The left knee jerk could not be elicited; the right was present. Plantar, cremasteric, and abdominal reflexes all were present. There was no impairment of sensation and no retention of urine. There was never any strabismus and no convulsions were noted. Two days before death there were slight inequality of the pupils and well-marked bilateral optic neuritis, more pronounced upon the right side. There was no nasal or aural discharge, and no pulmonary abnormality could be detected. The post-mortem examination revealed distinct inflammation of Peyer's patches, with decided enlargement of the mesenteric glands and solitary follicles. Nothing was found in the brain to give rise to the optic neuritis.

Disinfection of Typhoid Excreta.—Dr. W. Gilman Thompson (*Albany Medical Annals*, April, 1897) concludes as follows: 1. The best disinfectants of typhoid stools for practical use are: (*a*) 1 to 500 acidulated solution of corrosive sublimate; (*b*) 1 to 10 crude carbolic-acid solution; (*c*) chlorinated lime. 2. Owing to the possibility of injury to plumbing, the carbolic-acid solution is preferable wherever plumbing is concerned. The lime is best for country use in privies and trenches. 3. The disinfectant should be thoroughly mixed with the stool and left in contact with it for fully two hours. Enough of the disinfectant must be added to cover completely the stool with the solution. 4. The bed pan should be kept ready filled at all times with at least a pint of the disinfectant, into which the stool is at once discharged, and should be cleaned with scalding water and one of the disinfecting solutions. 5. Rectal thermometers, syringes, tubes, and all utensils coming in contact with any of the fæcal matter must be disinfected with the corrosive-sublimate or carbolic-acid solution. 6. After each stool the patient's perineum and adjacent parts should be washed and sponged with a 1 to 2,000 corrosive-sublimate solution. 7. Nurses and attendants should be cautioned to wash their own hands thoroughly and immerse them in a 1 to 1,000 corrosive-sublimate solution, after handling the bedpan, thermometer, syringe, or patient, or giving sponge or tub baths. 8. All linen and bedclothing used by the patient should be soaked in a 1 to 20 carbolic-acid solution and subsequently boiled for fully two hours. 9. Disinfection of the stools should be begun as soon as the diagnosis of enteric fever is established, and should be continued for ten days after the temperature has remained at the normal. 10. In localities where a proper drainage system is lacking, the stools should either be mixed with sawdust and cremated, or buried in a trench four feet deep after being covered with chloride of lime.

Eucalyptus Globulus in Strychnine Poisoning.—Dr. Monfrida Musmecin has found that a decoction of the leaves of eucalyptus globulus and a solution of a salt of strychnine formed a flocculent precipitate of a clear color, a solution of citron-yellow tint remaining above and the strychnine losing its bitter taste. This raised the question as to whether eucalyptus was an antidote for strychnine. The author carried out a number of experiments upon animals, to ascertain what effects would be produced by giving these two drugs together, and what antidotal power eucalyptus would exert after the development of the symptoms of strychnine poisoning. He found that when these drugs were given simultaneously the animal survived, while if the same amount of strychnine were given alone to an animal of the same kind and size, death would ensue. In another set of experiments the eucalyptus was given after convulsions had appeared, and then these became much less marked and even disappeared. From these experiments the writer believes that eucalyptus has a real antidotal action, and that a practical application of it should be made by employing a decoction for washing out the stomach in such cases. —*British Medical Journal.*

Sudden Death in the Puerperium.—Dr. Goltman (*Memphis Medical Monthly*, April, 1897), in an article on this subject, formulates the following deductions: 1. Pulmonary embolism is the cause of death in most of these cases. 2. It is rare, but so shocks a community when it occurs that it is advisable to take every precaution to guard against it. 3. Phlebitis, varicose veins, prolonged labor, hemorrhage, anæmia, sepsis, cancer, syphilis, etc., predispose to its production. 4. In the presence of peripheral thrombosis, etc., absolute rest must be enjoined, especially between the second and third weeks of the puerperium, as this is the disintegrating period of the clots. The danger should also be explicitly pointed out to both patient and attendants, thus insuring, to an extent, a healthy co-operation. 5. The extreme changes in the blood usually ascribed to pregnancy and the puerperium are erroneous, and not corroborated by modern investigation. 6. Sudden death from air embolism in the puerperium is doubtful from physiological, pathological, and rational standpoints. 7. Shock is both a direct and indirect cause of death in the puerperium, and should be guarded against. 8. Organic heart affections, kidney trouble, etc., are capable of producing death at any time, and should not be overlooked in the puerperium.

Puerperal Biliary Colic.—According to Dr. Eiermann, cases of biliary colic occurring after labor are rare. He relates one occurring in a primipara, aged twenty-nine, who suffered from albuminuria during pregnancy. Delivery was difficult, and a rupture of the perineum almost into the rectum occurred. In five days the œdema of the legs disappeared, but then the patient was seized with shivering and severe pain in the upper part of the abdomen. On the next day there was distinct jaundice, which disappeared in two or three days. There had been no previous history of gall stones. Eiermann attributed the colic to the suddenly altered pressure relations in the abdomen after labor. Gottschalk has seen nine or ten cases of gall stones in women in the puerperal state. In one the colic reappeared after a subsequent pregnancy, the patient having been free from it in the interval. The diagnosis may be difficult if there is no jaundice.—*Münchener medicinische Wochenschrift.*

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

New York, September 4, 1897.

THE MONTREAL MEETING OF THE BRITISH MEDICAL ASSOCIATION.

THE sixty-fifth annual meeting of the British Medical Association, at Montreal, during the present week, a special report of the first part of which will be found in another column, was an event in the medical history of Canada which will be long and pleasantly remembered by our neighbors across the border. The fact that it was the first time in the history of the association that the annual meeting was held outside the British Isles gave rise to some forebodings as to its success. While the number of members registered was, as might naturally be expected, smaller than is usual, those who proposed bringing the association to this side of the Atlantic have reason to be highly gratified. The visitors from abroad will return home with enlarged ideas of the Greater Britain to which many of them were previously strangers. Montreal is one of the most beautifully situated cities of the British empire, and has from its foundation in 1642 been devoted to medicine. Paul de Chomedey, Sieur de Maisonneuve, brought in his company the devoted Jeanne Mance, head of the little community of nuns nominated by the founders of the colony to nurse the sick. She founded the Hôtel Dieu, the oldest hospital in America, which remains to this day the greatest Catholic hospital in Canada.

The opening ceremonies, which were preceded by a service and sermon in the English cathedral, were highly interesting, and demonstrated the fact that a hearty welcome greeted the association, as Lord Aberdeen, the governor-general, expressed it, from every citizen of the dominion. The addresses of the president, Dr. T. G. Roddick, of Montreal, Dr. William Osler, of Baltimore, and Mr. T. Mitchell Banks, of Liverpool, which we are enabled, through the courtesy of the *British Medical Journal*, to present in full to our readers, were worthy of the authors and of the occasion.

Everything possible was done to make the meeting memorable. All the most interesting features of the city with its crowning glory, Mount Royal, were made attractive to the visitors. The thoroughness and care which marked all the arrangements for the convenience and comfort of the members were a pleasing and notable feature of the gathering. The extensive list of entertainments left nothing to be desired from a social point of view.

In the president-elect, Sir Thomas Grainger Stewart, of Edinburgh, the association will have a presiding officer whose fame is world wide. Edinburgh was selected as the next place of meeting, and the scientific position of the city, to say nothing of its proverbial Scottish hospitality, indicates the wisdom of the selection.

Although the constitution of the association prevents any but British subjects from enjoying the privileges of membership, the American profession was well represented among the guests, and those who were thus honored expressed themselves as well pleased with the reception they received.

THE ANTITOXIN TREATMENT OF DIPHTHERIA.

THE claims that have been put forward as to the efficacy of the antitoxin in the treatment of diphtheria have not been successfully assailed from any quarter, and the affirmative evidence afforded by statistics on the largest scale and from the most diverse sources has not been in the slightest degree shaken. On the contrary, the evidence has steadily increased and the claims have been fortified. In the face of the facts it is difficult to understand the mental attitude of the small minority who are yet willing to antagonize a method of treatment that, according to almost universal testimony, has now proved its worth for more than three years, and whose employment has resulted in the saving of many lives and the sparing of many days of illness. To the wholly unprejudiced and impersonal reports of the two collective investigations instituted by the American Pediatric Society and the earlier report of the collective investigation of the Berlin Society for Internal Medicine, may now be added the report of one of the most exhaustive and elaborate statistical studies of the treatment of diphtheria with the antitoxin, recently issued by the medical superintendents of the hospitals of the London Metropolitan Asylums Board (*Lancet*, June 5, 1897).

According to this report, the total number of cases treated in the several hospitals under the control of the board during the year 1896 was 4,175, with 871 deaths, or a mortality of 20.8 per cent. Of the whole number received in 1896, 2,764 (71.3 per cent.) were treated with the antitoxin, with 717 deaths—a mortality of 25.9 per cent. In the year 1894, before the employment of the antitoxin had been instituted, there occurred among 3,042 cases 902 deaths (29.8 per cent.) —a saving thus of 8.8 per cent., or 365 lives. The antitoxin treatment was not resorted to in moribund or hopeless cases, or in those of doubtful nature, or so mild in character as to seem not to require any specific treatment. The best results of the treatment were obtained when it was instituted early, and the value of these results is strengthened by the fact that the proportion of the very young was much greater among those treated with the antitoxin than among those not so treated. Another evidence of the greater comparative severity of the cases in the antitoxin series is to be found in the fact that in this group the per-

centage of laryngeal cases was 17.6 per cent., as compared with 1.9 per cent. in the non-antitoxin series. A comparison between the age incidence and mortality of all cases of diphtheria treated in 1896 (whether by the antitoxin or not) and those of the cases treated by the board in 1894, not only shows that the total mortality was less by 8.8 per cent. in the year first named, but the difference is the more accentuated in accordance with the earliness of the period at which the cases came under observation.

It is interesting to note that clinical rather than bacteriological evidence was taken as the criterion in arriving at a diagnosis, and also that in only 4.5 per cent. did the latter fail to confirm the former. One of the most striking effects of the use of the antitoxin was observed in the diminution of severity induced in cases in which the larynx was involved. In 1894 the mortality in the hospitals of the Asylums Board was in laryngeal cases, 62 per cent.; in 1896 it was 29.6 per cent. In 1894 the mortality after tracheotomy was 70.4 per cent.; in 1896 it was 41 per cent., although in the latter year the proportion of laryngeal cases submitted to tracheotomy was 56, as compared with 41 in 1894. The proportion of cases in which albuminuria and paralysis respectively occurred was greater in 1896 than in 1894, but this discrepancy is to be explained by the increased attention paid to the detection of albuminuria, while the greater proportion of cases of paralysis is viewed as confirmatory evidence of the larger proportion of survivals from the initial dangers of the diphtheria virus.

The average dose of the antitoxin employed was two thousand units per injection, and the average number of injections 2.3 for each patient. Often this dose was considerably exceeded, and some cases received many injections. Untoward effects incidental to the injections were noted in only a small proportion of cases. Thus a rash was observed in 35.2 per cent., joint-pains in 6.5 per cent., pyrexia in 19.8 per cent., abscess in 1.2 per cent.

In a summing up of the results yielded by the clinical and statistical observations made in connection with this study, the advantages achieved in the cases of diphtheria treated during the year 1896 are stated to be: 1, A great reduction in the mortality of cases brought under treatment on the first three days of illness; 2, the lowering of the combined general mortality to a point below that of any former year; 3, the still more remarkable reduction in the mortality of the laryngeal cases; 4, the uniform improvement in the results of tracheotomy; and 5, the beneficial effect produced on the clinical course of the disease.

THE RELATION BETWEEN VACCINATION AND TUBERCULOSIS.

According to the Berlin correspondent of the *British Medical Journal*, July 3, 1897, the scientific committee for all matters relating to medicine and public hygiene has replied in the negative to the question asked by the medical department of the Prussian ministry of education—whether it is possible for vaccination to cause a tendency to tuberculosis and scrofula, and, if so, under what conditions. The committee takes the ground that since the discovery of the tubercle-bacillus as the cause of tuberculosis vaccination cannot be held responsible as a cause of that disease.

As to the allegation frequently made that vaccination produces a disposition to tuberculosis, it is often assumed that certain diseases, *e.g.*, diabetes, measles, whooping-cough, and debilitating diseases generally, cause such a predisposition. The question arises: Can the short, feverish attack produced by vaccination be included among these? It is to be remembered that tuberculosis is the most widespread disease known, so that of course a number of vaccinated persons must become its victims. There is, however, no evidence that would permit recognition and proof that in any case of tuberculosis or scrofula developing after vaccination the disease is a consequence of the prophylactic procedure, or that would go to show that an individual after vaccination is more predisposed to scrofula and tuberculosis than are unvaccinated persons.

Mortality statistics on a large scale also go to show that vaccination is not even indirectly a cause of tuberculosis. Tuberculosis is the most frequent cause of death, and if really increased by compulsory vaccination the mortality should have increased since the introduction of the latter. The reverse, however, is the case. In spite of strictly enforced revaccination, the mortality from tuberculosis in the Prussian army has diminished. It is possible that untoward complications of vaccination, such as erysipelas, may weaken the organism and lower its resisting power to the invasion of the tubercle-bacillus. Neither is it to be denied that when tubercle-bacilli have already found their way into the organism vaccination may be followed by their increase or spread.

A Useful Medical Society.—The McKean County (Pa.) Medical Association is a live organization, which is awake to the interests of the community and does all possible to protect it against injury by quacks. The society has recently had three advertising itinerants, who unwarily attempted to ply their trade in Bradford, arrested and driven from the place. This is an example worthy of imitation by other county societies in all States where an efficient medical-practice law exists.

Anthrax in Pennsylvania.—As the result of an investigation undertaken at the instance of the Pennsylvania State board of health, Dr. Leonard Pearson, State veterinarian, reports that the death of the four men in Jefferson County under dubious circumstances was due to anthrax, derived, it is believed, from the handling of infected hides imported from Asia. A number of cattle also have been affected. The hides in question had been treated with arsenic and they had been washed in a neighboring creek, and it was thought that the trouble might have been due to drinking the polluted water.

News of the Week.

Navy Department, Bureau of Medicine and Surgery, Washington, D. C.—Changes in the medical corps of the United States navy for the week ending August 28, 1897. August 25th.—Assistant Surgeon W. M. Wheeler detached from the *Marietta* and ordered to the *Wheeling*, September 2d; Passed Assistant Surgeon G. Rothganger detached from the *Wheeling* and ordered to the *Marietta*, September 2d.

Italian Society of Laryngology, Otology, and Rhinology.—The third biennial meeting of this society will be held in Rome, commencing on October 28th. The subjects for the set discussions are: The value of autoscopy in the diagnosis and treatment of laryngeal affections; adenoid vegetations in Italy; physiology of the middle ear. The president of the association is Dr. V. Grazzi, and the secretary Dr. A. Fasano, of Naples.

A Tiny Midget.—From St. Louis comes the report of the birth of a child weighing one pound and measuring eight inches in length.

The Milk Supply of New York. — According to the report of the board of health for 1896, the number of cows which furnish milk for this city is 115,570. There are seven thousand places in the city where milk is sold both wholesale and retail. The system of granting permits to venders of milk, which went into effect at the commencement of the year 1896, has been found to be of great value. As a result of this, together with the application of the tuberculin test to milch cows, there is now a system of milk inspection which is as perfect as is possible at the present day and with the present force. The milk permits are in force during the pleasure of the board of health, which revokes them on the second trial and conviction for the sale of "adulterated milk," that phrase meaning milk containing more than eighty-eight per cent. of water or fluid and less than four per cent. of milk solids, or less than three per cent. of fat, milk drawn from animals fed on distillery waste, milk from which any part of the cream has been removed, and milk from cows kept in crowded or unhealthy places. In 1895, in the samples of milk which were tested, three hundred and ninety-three cases of adulteration were discovered, while last year the inspection and test showed only two hundred and thirty-three. The number of arrests in 1895 for selling adulterated milk was four hundred and eight; in 1896 there were only two hundred and twenty.

Efforts to Abate the Spitting-Nuisance in Jersey City.—The Jersey City board of health has passed an ordinance, making expectoration on the floors or platforms of trolley or horse cars or public conveyances of any kind punishable by the imposition of a $10 fine. The ordinance was recommended by the health inspector, and its passage was urged by many women, who complained that the filthy habit had frequently caused the destruction of their dresses.

Obituary Notes.—Dr. Benjamin R. Whitaker, of Phenixville, Pa., died at Philadelphia on August 18th, at the age of fifty-three years. He was a graduate of the medical department of the University of Pennsylvania, and served during the war of the rebellion as surgeon to the one hundred and fourth regiment, Pennsylvania volunteers, and during the riots of 1877 as surgeon to the Pennsylvania national guard. — Dr. De Witt Clinton Hough, of Rahway, N. J., died on August 25th, of paralysis. He was born in 1827 at Point Pleasant, Bucks County, Pa. He graduated at Jefferson Medical College in the class of 1847, and went to Rahway in 1857. He was for three years the chief surgeon in the seventh New Jersey volunteers, ranking as major. Dr. Hough was mayor of Rahway in 1867 and 1868, and also served in the legislature for three terms.—Dr. John R. Cabell, of Danville, Va., was assassinated on August 26th by one of his tenants, whom he had notified to give up the farm on which he lived on the ground of some irregular transactions. Dr. Cabell was a graduate of the medical department of the University of Virginia in 1850.—Dr. Walter McKenzie, of Nanuet, N. Y., committed suicide by taking morphine on August 26th. He was thirty-seven years of age, and was a graduate of Bellevue Hospital Medical College in this city.

International Congress of Legal Medicine.—The meeting of the International Congress of Legal Medicine, held at Brussels from August 2d to 7th, was a great success. The French government was represented by Professor Brouardel, dean of the Paris Medical Faculty, and by Drs. G. Pouchet, Motet, Mosny, Thoinot, Descoust, Vibert, Ogier, and Socquet; that of Sweden by Dr. Johan-Mauritz Aspelin, of Stockholm; the Swiss State council by Professor Gosse, of Geneva; the Spanish government by Dr. Enrique Simancas; and the Russian government by Prof. Demetrius von Kossorotoff, of St. Petersburg. The New York Society of Legal Medicine sent Dr. Valentine as a delegate. The meetings of the congress were attended by a large number of prominent members of the legal and medical professions and of the magistracy. Important discussions took place on criminal lunatics and public asylums, poisoning by carbonic oxide, professional secrecy in relation to the law, the medico-legal value of subserous ecchymoses, the glycogenic function of the liver in relation to medical evidence, cadaveric spasm, the internal factors of cadaveric decomposition, the lung test of life after birth, poisoning by sulphuretted hydrogen, the place and duty of the medical expert in relation to poisoning by meat, hypnotism in its relation to crime, and responsibility—particularly partial responsibility. The next meeting of the congress will be held in Paris in 1900.

British Medical Journal.

An Old Swindle Revived.—Some man is working a very successful swindle in the suburbs of this city, by means of a new application of an old trick. He pretends to be a physician from some other place, who has a sick servant needing hospital care. He calls on one of the attending staff of the hospital and gets

a letter of introduction to the matron. Armed with this he goes to the hospital and makes arrangements for the reception of the patient, paying in advance with a check which is larger than the amount required. The matron gives the change in money, and finds a few days later that the check is worthless.

The Sanitary Institute of Great Britain, the twenty-first anniversary of the formation of which was recently commemorated by a dinner in London, now numbers twenty-one hundred members and associates, and its annual income is more than £6,000.

Cholera is spreading in Bombay, many of the English troops stationed there having been attacked. In spite of the warning of the plague, the sanitary condition of the city is said to be most unsatisfactory.

The Medical Society of the County of Queens.—The midsummer quarterly meeting of this society was held at Long Beach, Long Island, on Tuesday afternoon of this week. The main subject for discussion was "The Diagnosis and Treatment of Fractures and Dislocations." Many medical men not members of the society were present, and the meeting was regarded as a very successful affair.

Texas Fever is reported to be spreading among the cattle in southwestern Iowa. The cattlemen have become greatly alarmed and have appealed for assistance to the State authorities.

Quarantine against Montreal.—The telegraph reports that the health board of Ottawa has established a quarantine against trains from Montreal, because of the small-pox in the latter city.

A Confidence Game which has been successfully played upon the ambitious physicians of a city in Nebraska is so simple and withal so certain in its results that we can commend it warmly to the God-fearing managers of all the hospitals in the country. The hospital was one of several in the city, and, the number of inhabitants not being unlimited, it suffered somewhat from the competition of unscrupulous rivals who underbid it and secured most of the wealthy sick. After three or four years of ups and downs the hospital was reorganized and a new medical staff was appointed. As soon as the new doctors were comfortably settled in their places and had become accustomed to their new titles, the members of the board of trustees called upon them personally, told them of the financial straits of their beloved institution, and intimated that it would have to close its doors unless more money was forthcoming. To avert such a calamity, which would fall so heavily on the suffering poor, each member of the new medical board drew his check for an amount which he thought would be sufficient to make him secure in his new place, and so the hospital expenses were met, and the trustees were encouraged to remodel one of the buildings. The first of this year a number of these guileless medical men, constituting a majority of the attending staff, received notices from the board of trustees that their services were no longer required, a new staff having been appointed. The checks of the new appointees will soon be called for, and we would suggest to them that, if they desire to continue their charitable labors longer than a twelvemonth, they had better signify their intention of making an annual contribution to the good cause.

Punishment of a Clerical Medical Practitioner.—The right of a clergyman to attempt to heal by prayer and the laying on of hands has been questioned in New Orleans, where a Catholic priest has been prosecuted for a violation of the State medical-practice law and of a city ordinance relative to clairvoyants, unlicensed practitioners, and the like. The clergyman, while willing to pray over those who desired his services, did not pretend to be able to cure disease and did not demand any payment for his services, although accepting such small sums as his callers chose to give him. The charge of violating the State law was dismissed, but a fine of twenty-five dollars was imposed for violation of the city ordinance.

A New Narcotic.—It is reported that the physicians in the Mexico insane asylum have discovered that the seeds of the sapodilla furnish a reliable narcotic which produces a quiet sleep followed by no unpleasant after-effects.

The Canadian Medical Association.—The thirtieth annual meeting of this society was held in Montreal on Monday, August 30th. On account of the meeting of the British Medical Association the following day, it had been decided that no scientific papers would be read, and the meeting was held only for the transaction of the necessary executive business. The president of the association, Dr. V. H. Moore, of Brockville, delivered the annual address. After thanking the members of the society for the honor of an election to the highest office in their gift, he addressed a few words of greeting to the members of the British Medical Association who had come into the meeting, and also to the numerous American physicians who were present. Medical men in the United States, he said, "are industrious, persevering, and energetic, quick to see, ready to adopt, and eager to carry out any and all improvements and discoveries to a successful or final issue; hence it is not surprising that they have made such progress." He then took up the main portion of the address, which was devoted to the condition of medical and other branches of education in Canada at the present day. In closing he again welcomed the members of the British Medical Association on behalf of the medical profession of Canada, and he said that the citizens of Montreal, who are so noted for their hospitality, and indeed all Canadians, would do their utmost to make the stay of their brethren in the country as pleasant and as profitable as possible. The election of officers resulted in the choice of the following: *President*, Dr. J. M. Beausoleil, Quebec; *Vice-Presidents*—Drs. A. McPhedraw, Toronto; C. S. Parke, Quebec; R. A. McKean, Glace Bay; P. R. Tuch, St. John, R. McNeil, Stanley Bridge, J. R. Jones, Winnipeg; F. C. McWheen, Lethbridge; and J. Tunstall, Vancouver; *General Secretary*, Dr. F. N. G. Starr, Toronto; *Treasurer*, Dr. H. B. Small, Ottawa.

Society Reports.

TWELFTH INTERNATIONAL MEDICAL CONGRESS.

Held in Moscow, August 19, 20, 21, 22, 23, 24, 25, and 26, 1897.

(Special Report by Direct U. S. Cable to the Medical Record.)

GENERAL SESSIONS.

(Continued from page 317.)

Third Day—Thursday, August 26th.

THE third and closing general session of the Moscow congress was held on Thursday afternoon, under the presidency of Sir William MacCormac, of London. The attendance, as is usual in gatherings of this kind, was much smaller at this session than at the opening one, though larger than at the intermediate session on Sunday afternoon.

The Cell Nucleus.—PROFESSOR LUKIANOV, of St. Petersburg, was the first orator of the day. His address was devoted to a consideration of the effect of inanition upon the nucleus of the cell and to the conclusions derived from the results of this study as to the functions and importance of the nucleus. Cellular morphology, he claimed, is the most important of biological studies, surpassing all other studies as regards the information which it gives us concerning the processes of life. This is true even as regards unicellular organisms, but more especially so when we study the morphology of the cell in multicellular beings. In many respects bacteria are analogous to cell nuclei, especially as concerns the changes which they undergo as a result of inanition. In the course of a long series of experiments conducted in the orator's laboratory, it had been discovered that bacteria lose fifty-one per cent. of their substance during the first six days that they are deprived of necessary sustenance, but then attain an equilibrium which is maintained practically unchanged during from forty to eighty days of further culture. In the same way it has been found that, when an animal is suffering from inanition, the nuclei of its cells lose more than one-half of their substance without undergoing degeneration. In rabbits which had been starved for a certain period, the loss in weight was thirty-five per cent., the size of the pancreas was reduced three per cent., the cells were diminished in size about thirteen per cent., but there was no change visible in the structure of the nuclei. From this the speaker concluded that the nuclei are independent of the cell body. If, however, the nucleus is autonomous, it must necessarily have a composite structure. That it has a selective action of its own has been proved by a number of experiments in feeding animals with different substances. Animals were fed exclusively on lard, or sugar, or peptone, or albumin, or hay, and it was found that the nuclei varied in size according to the kind of nutriment employed. The nuclei also multiply differently according to the nature and amount of the nutritive material supplied to them. But this multiplication or reproduction of the cell nucleus occurs entirely independently of the cell body. The cell is therefore not an elementary body. This, Professor Lukianov ventured to believe, is a new truth, an end-of-the-century discovery which will serve as a basis for the working out of many biological problems during the years of the twentieth century which is about to dawn, and which we have every justification for believing will be so productive of knowledge and of advance in every department of science.

The Present Modes of Treating Consumptives and their State Control.—PROFESSOR E. V. LEYDEN, of Berlin, said that he had no apology to offer for selecting such a well-worn subject, for the misery in the world caused by pulmonary tuberculosis is so great that until we have solved the problem we can never tire of discussing the means of its prevention. He proposed to discuss especially the institutional treatment of consumption and see in what way its benefits may be extended to the poor, who at present are almost wholly debarred from participation in them.

The ancient belief in the incurability of pulmonary tuberculosis was thrown down by Brehmer in 1855, when he established his famous sanatorium in Görbersdorf and began to restore to society pulmonary invalids who had been condemned to death by physicians and friends. The elements of this method of cure are: the choice of a healthful climate, abundant nourishment, fresh air, hardening of the body and systematic exercises, rest and passive movements, psychotherapy and discipline of the patient, and lastly the use of drugs in certain cases.

But before considering these points in detail the speaker would dwell briefly on the prophylaxis of tuberculosis. Assuming as proven that tuberculosis is a contagious disease and that the agent of infection is Koch's bacillus, he said that contagion may be direct, indirect, or from animals. Direct contagion is usually easily followed, but the path of indirect contagion by means of dust, infected vessels, clothing, or other objects of various kinds, is often most obscure. Infection from animals through milk, butter, and meat is, he held, much more frequent than physicians and the public are apt to believe. He laid but little stress on heredity, for he believed that in most cases the disease was transmitted to children by contagion from their parents, and not by inheritance. Our preventive measures are conducted along two lines: the prevention of infection, and the strengthening of the body to resist the attacks of the pathogenic agent. The latter can be effected by bringing up children with Spartan severity and by shunning every approach to coddling. It is along this path that we may hope for success, for the attempt to avoid the agent of contagion must necessarily fail and will result only in causing a bacillophobia that is unworthy of a rational people. The public is justly suspicious of attempts of the sanitary authorities to suppress this disease. Certain precautionary measures, such as the destruction of sputa and the avoidance of intimate association of the sick with the well, are of course necessary, but they should be carried out otherwise than by the power of the police. In this connection the speaker took up the question of the alleged danger of sanatoria for consumptives, and denied with emphasis that any such existed in a properly conducted institution.

The medicinal treatment, he said, may be considered under three heads, viz., pharmacological products, opotherapy, and orrhotherapy. While admitting the efficacy of certain drugs of the creosote order, he denied that they had any specific action. Opotherapy with "pulmonin" he dismissed with a word of contempt. He then took up the history of tuberculin and other serum products, and said that they are all as yet only on trial and their actual therapeutic value remains to be proven. There is, however, a very present danger that, in looking forward to ultimate success by this means, we come to value less highly the very efficacious means we have at hand in the institutional treatment of consumption, that is, the hygienic and dietetic therapy of the disease.

Taking up the several points in this treatment, he spoke first of climate. Great faith has for a long time been placed upon a change of climate for the phthisical, especially a change to an elevated region where consumption is seldom encountered among the natives. While valuing highly the climatic advantages

of high altitudes, the speaker warned his hearers that there is no actual immunity against tuberculosis in these regions, and we cannot depend upon any climate as in itself directly curative of this disease. Neither are the hills the only regions where benefit may be obtained, for the seashore and southern climates are equally efficacious in many cases. The chief disadvantage of a warm climate is that it unfits the sufferer for a life in his northern home after the cure of his tuberculosis. The speaker quoted Dr. Knopf, of New York, who disbelieves in the specific action of any particular climate and recommends that sanatoria be established within easy distance of the large centres of population.

The assumed specific action of fresh air in tuberculosis is also one of the myths of medicine. It has no such action, but its value is a purely hygienic one, since it aids greatly in strengthening the organism and rendering it more resistant to the attacks of the pathogenic organisms. The air should be pure, as free as possible from dust, not liable to great and sudden changes of temperature, and the place should be free from violent storms.

Of great importance is the nourishment of the phthisical. The time has long passed when men treated consumption as they did other pyretic affections, by a low diet. Experience has shown that the more food the consumptive takes and digests the better are his chances of recovery. Formerly great stress was laid upon the consumption of large quantities of fats, cod-liver oil, cream, and the like, and also upon the taking of a plentiful supply of alcohol. The latter is now given in much smaller quantity, for it is neither a suitable food nor a destroyer of the pathogenic germ. It is useful to cheer the patient and to stimulate his appetite, but in no other way, and it may be harmful by favoring hæmoptysis. We do not even place as much reliance on fats and milk as in former times, but we accommodate the diet to the needs and the taste of the patient, taking care only to see that it is so composed as to furnish calories enough to more than compensate for the daily loss.

The value of psychotherapy in tuberculosis must not be underestimated. The patient should be encouraged to hope for a cure and should be taken into the physician's confidence to the extent that he may understand the object of each of the measures adopted, so that he may be able to further their good effect by his own co-operation and may be inspired with confidence in the methods employed. The discipline of the institution, however, should not be too strict, but the patients should be allowed all liberty that is consistent with the proper execution of the hygienic and dietetic rules.

Finally, v. Leyden said, we have to consider the hardening process, and he had reserved the discussion of this for the last in order emphasize its importance. This is the point in the hygienic and dietetic method which in a measure marks its superiority over the specific treatment. The latter combats the pathogenic agents and its success is assured only when it has completely and permanently destroyed the tubercle bacilli so as to secure a lasting immunity for the organism. The hardening process, however, so strengthens the diseased body that it acquires sufficient resisting power not only to tolerate the disease but to overpower it, and so gain a complete and enduring victory over it. Among the measures by which this is effected are a life in the open air, living in airy apartments, and sleeping with open windows. Hydrotherapy is another powerful agent in this process, and consists in cold sponging, showers, and short cold plunges. Further exercises in the open air are necessary, such as methodically prescribed hill climbing, similar to Oertel's "Terraincur," and various sports—riding, rowing, golf, and the like. Overheating is, however, to be avoided, as it may cause bronchitis or even hæmoptysis. The rest cure is suitable only for very weak patients, whom we should endeavor to strengthen as rapidly as possible and then subject them to a graduated hardening process.

It has been asked whether similar results cannot be obtained by following out all the prescriptions of diet, exercise, etc., outside of an institution, and in reply the speaker said they could, though with much greater difficulty. In some cases the patient has such a repugnance to institution life that it is necessary to give him outside treatment. Sometimes, however, this repugnance can be overcome by firmness on the part of the physician, and once the patient has made a trial of the sanatorium he is generally satisfied to remain.

Naturally, however, the benefits of this treatment can be enjoyed by only a few whose means will permit, and the thousands and thousands of the poor are debarred from the privileges; but if the combat against tuberculosis is to become general we must bring the benefits of the institution treatment within reach of the poorest by the establishment of special sanatoria for the people.

Much interest has of late been aroused in Germany in what has been called the "sanatorium movement." This movement dates from about ten years back, being stimulated by the discussion of the question of the isolation of consumptives. The idea of forcible segregation of the tuberculous was happily abandoned as being only apparently humane and really inhuman in its consequences, but it resulted in the determination to establish public sanatoria where the poor could receive the same care as the well-to-do in private institutions. At present there are in Germany twenty sanatoria in course of construction or already in working order. Almost all of the old-established sanatoria now have annexes of more modest character, where those of small means can be treated, and many of the large cities of Germany have undertaken the establishment of hospitals for consumptives.

The speaker then referred to what had been done in this direction in other lands, notably in England, where the Royal Hospital for Diseases of the Chest was established in 1814 and the Brompton Hospital in 1841. He mentioned also various sanatoria in the United States, France, Austria, and Russia, where much is being done. v. Leyden himself had devoted much time and labor to the extension of this sanatorium movement. In 1894 he delivered a public address, before the International Hygienic Congress at Budapest, on "The Care of the Tuberculous by the Large Cities," and a year later read a paper on "The Necessity of the Establishment of Public Sanatoria for Sufferers from Pulmonary Disease" at a meeting of the National Public Health Association. After detailing the plans of the Berlin-Brandenburger Heilstätten-Verein, established for the purpose of erecting free sanatoria for consumptives, which has already made satisfactory progress, the speaker closed with the hope that soon all the countries of the civilized world would be dotted with hospitals for consumptives which might serve as worthy monuments to the memory of the philanthropists of the nineteenth century.

New Horizons in Psychiatry.—Prof. Cesare Lombroso, of Turin, was the last orator. When he stepped forward on the platform he was received with long-continued and repeated rounds of applause, just as his name was cheered to the echo when it was read, on the first day of the congress, among those of the national presidents. The doctrine of criminal anthropology, of which the Turin professor is the most distinguished apostle, numbers many of its most enthusiastic and active supporters among Russian men

of science. In the introduction to his subject the speaker said that by the term "new horizons" he meant new applications of the science of psychiatry, namely, the application of the facts of this branch of learning to a study of abnormal man, of the criminal and degenerate. All new sciences meet with great opposition at first, and it is best that they should. This new science had not escaped the usual fate; it had even been denied the distinction of being a science. But there is, the speaker maintained, much true, earnest, scientific work being done in it. The tendency of the science is not to undermine the penal code, as some legislators have imagined, but its aim is solely to protect diseased humanity; it is to turn society from its cherished system of vengeance for wrongs done to it by irresponsible beings, to a policy of correction and of prevention of crime. Unfortunately, and this is a fact which has been used by opponents to discredit the science of criminal anthropology, pathology is of little or no help in the study. But there is the same drawback in the study of many nervous diseases, for in perhaps the majority of them, the so-called functional nervous diseases, there are no definite lesions discoverable with the aids at our command. There is hope, however, for the future in the new theory of the neuron. In this theory of independent movements of the neurons we find a very satisfactory explanation of the phenomena of sleep, of hypnotism, and of memory. The fact that in dealing with supposed psychical states we are dealing with pure hypotheses is one that tends to discourage observation, but it should not. We ought to study carefully all modifications of the psychical state, for the discoveries which this may lead us to are incalculable in their importance. An explanation of telepathy or mental influence acting at a distance is possibly to be found in a polarization of the molecular elements of the brain substance. This science, this study of psychiatry, which has been but begun in the nineteenth century, will be handed down as a legacy to the twentieth, and the development which it may attain and the benefits to the human race which may flow from its discoveries are beyond our powers to foresee—indeed, beyond even the powers of imagination.

First Award of the Moscow Prize.—Professor Virchow then proposed, amid universal expressions of approbation, that the first Moscow prize, established by the municipality of Moscow and to be awarded at each recurring international congress, be bestowed upon Henri Dunant, the founder of the Red Cross Society, in recognition of his inestimable services to humanity. This proposal was accepted with acclamation and prolonged cheers.

A telegram was then sent to the Tsar, informing him of the close of the twelfth international congress, and thanking him for his liberality which had made this meeting possible.

Professor Virchow then rose again, and in eloquent words thanked Professor Sklifosovsky on behalf of the members of the congress for the cordial reception which had been accorded them, and he assured the president and all his colleagues, to whose untiring efforts the success of the meeting was due, that never would the foreign congressists forget that Russian hospitality, of which they had so often heard and which now they had had the opportunity to experience in their own persons.

Professor Sklifosovsky replied with tears in his eyes, and then turning to his brethren on the committee, addressed them in Russian, saying that it was to them the thanks were due. His part had been a feeble one, though he had performed it to the best of his powers. But the main part of the labor had been theirs, and if any praise were due for what had been done it was to them that it must be accorded.

Sir William MacCormac followed with a brief address of thanks on behalf of his English-speaking colleagues.

Professor Sklifosovsky then declared the congress adjourned, and wished all present *au revoir à Paris!*

(To be continued.)

BRITISH MEDICAL ASSOCIATION.

Sixty-Fifth Annual Meeting, Held at Montreal, Canada, August 31, September 1, 2, 3, 1897.

Special Correspondence of the MEDICAL RECORD.

GENERAL SESSIONS.

First Day—Tuesday, August 31st.

Dr. T. G. Roddick, M.P., president of the association, was called to the chair at 3 P.M.

Addresses of Welcome.—Mr. Wilson Smith, mayor of the city of Montreal, expressed a hearty welcome in the name of the metropolitan city of Canada to the members and guests of the British Medical Association. He alluded to the pleasure the citizens felt when Montreal had been selected as the meeting-place. It seemed to him peculiarly appropriate that in this great year, when the jubilee of Queen Victoria's reign had been so enthusiastically honored by the colonies of Great Britain, such an opportunity should be afforded the members of the medical profession to become acquainted with the Greater Britain. He trusted the members of the association would, by visiting the different parts of Canada, become much and favorably impressed with the resources of the dominion, in order that they might carry back to the people unto whom it was their pleasure to minister a true and intelligent account of the magnitude of this part of the British empire. He wished them to know for themselves that this was not a land of ice and snow, but a dominion of great natural resources and with a climate second to none in the world.

His Honor, the lieutenant governor of the Province of Quebec, Sir Adolphe Chapleau, said he was a Britisher at heart, and on behalf of the province he cordially welcomed the association to Quebec. The legislative grant toward defraying some of the expenses of the meeting was only an outcome of the hospitality which was a distinguishing characteristic of the two great races which occupied the province. In this auspicious jubilee year, the meeting being held outside the British Isles was a great and good omen of the coming closer union between the motherland and her colonies. He eloquently reviewed the history of the association, and paid a eulogistic tribute to the scientific work it had accomplished. In conclusion, he assured the members of the association that while they sojourned within the borders of the province they were to be partakers in that freedom which was the great cornerstone on which the hopes and aspirations of true Canadians rested.

The Earl of Aberdeen, governor-general of Canada, said his was the third speech, so the association might consider itself thrice welcome. He indorsed all that had previously been expressed in welcoming the members and guests of the association to Canada.

Dr. J. G. Adami, of Montreal, then introduced the accredited delegates to the association.

President's Address.—Dr. T. G. Roddick then delivered the president's address (see page 325).

Lord Lister moved a vote of thanks to Dr. Roddick for his valuable and eloquent address.

Sir James Grant, of Ottawa, in seconding the resolution, expressed the pride and gratification which all Canadians felt at the visit of the association to the dominion. They were also pleased to see the visitors

from the other side of the line. They were one people, the only difference being that the progenitors of their American friends landed on Plymouth Rock, while the progenitors of the Canadians paddled up the St. Lawrence in order that they might enjoy under the British flag the principles of civil and religious liberty. He made a graceful allusion to the presence of Professor Richet, and congratulated Dr. Roddick on his address. With respect to the question of interprovincial registration, or a central examining board, he was sure the time was not far distant when an agreement would be arrived at.

Dr. Saundby briefly expressed the obligations of the association to the governor-general, Lieutenant-Governor Chapleau, and the mayor for their presence.

The meeting then adjourned.

In the evening a soirée was held at Laval University.

The Work of Pasteur and the Modern Conception of Medicine.—Prof. Charles Richet, of Paris, the delegate of the French government and of the Faculty of Medicine of Paris to the association, addressed the company on this subject. He first gave a sketch of the life of Pasteur, and then reviewed briefly his work and its influence on the doctrines of the microbic theory of disease, of antiseptic surgery, and of orrhotherapy.

At the conclusion of this address there followed a reception by the Earl of Aberdeen, the governor-general of the dominion.

Second Day—Wednesday, September 1st.

The chair was taken at 3 P.M. by the president, Dr. T. G. Roddick, M.P.

The address in medicine was delivered by Dr. William Osler, of Baltimore (see page 333).

Dr. Stephen Mackenzie, of London, moved, and Dr. A. Jacobi, of New York, seconded a vote of thanks to Dr. Osler.

At the conclusion of the address a special session of convocation of McGill University was held, the chancellor, the Right Honorable Lord Strathcona and Mount Royal presiding. The honorary degree of LL.D. was conferred in due form upon the following distinguished members of the profession now in attendance at the association meeting: Lord Lister, Sir W. Turner, and Messrs. Broadbent, Gaskill, McAllister, Watson Cheyne, Henry Barnes, and A. G. Wheelhouse.

The meeting adjourned after formal announcements had been made.

A reception was tendered to the members and guests of the association on Wednesday evening by Lord Strathcona and Mount Royal.

SECTION IN SURGERY.

First Day—Wednesday, September 1st.

The Teaching of Surgery.—Mr. Christopher Heath, F.R.C.S., of London, chairman of the section, delivered the annual address. After a brief introduction, he referred to the two subjects which were to be discussed at this meeting, viz., (1) Appendicitis and its surgical treatment, and (2) the treatment of cancer of the rectum, with special reference to the high operation, and then continued:

"Nothing, I venture to think, is more remarkable than the recent progress of abdominal surgery. Twelve years ago I was engaged in editing a 'Dictionary of Practical Surgery,' and neither appendicitis nor the operation for removal of the rectum, with which Kraske's name is connected, was mentioned in it, although I had the assistance of the leading London hospital surgeons. Kraske's original paper, I may mention, was published in 1885, and is referred to in Ball's work on the rectum, published in 1887, and in most surgical works since that date. The subject of appendicitis, so far as British surgery goes, dates from a paper read before the Royal Medical and Chirurgical Society in February, 1888, by Mr. Frederick Treves, though the title of it was 'Relapsing Typhlitis treated by Operation.' In August of the same year Mr. Treves opened a discussion on 'Surgical Treatment of Typhlitis,' at the meeting of the British Medical Association at Leeds, and subsequently published his address with additions and alterations in the form of a monograph, entitled 'The Surgical Treatment of Perityphlitis.' I do not know to whom we are indebted for the hybrid term 'appendicitis,' but it did not appear in the index to the *British Medical Journal* before 1891.

"But it is not merely in these two departments that progress has been made. The surgery of the kidney and of the liver has advanced *pari passu* with that of the hollow viscera, and the labors of Morris and Robson in England, and of Keen and others on this side of the Atlantic, have done much for the relief of suffering and the prolongation of life.

"Looking back over forty years of professional life, nothing surprises me more than the change which has come over the treatment of calculus. In my student days, to see Fergusson cut for stone by the lateral method was to witness an operation as near perfection as was conceivable, and the dexterity and rapidity with which the calculus was extracted were marred only by the frequency with which death from septic causes spoiled the skill of the surgeon. To have one's first lithotomy was an event in the life of the young surgeon, and every now and then a reputation was spoiled by some *contretemps* in the public performance of the operation. Later, I was the frequent witness of my colleague Henry Thompson's skill in using the lithotrite to break up the calculus in a series of 'sittings.' Then came 'litholapaxy,' or rapid lithotrity, which we owe to Bigelow, the great American surgeon; and, lastly, that recurrence to the old high or suprapubic operation which was due to the Scandinavian surgeon Petersen. Hence the student of to-day rarely if ever sees a perineal lithotomy, and as a consequence his interest in the anatomy of the parts concerned in the operation has greatly diminished. Possibly the surgeons of the last generation laid too much stress upon anatomical details, but it is somewhat remarkable to find how little anatomy seems to serve for practice in the present day.

"I am told by those who are teaching anatomy now that it is difficult to get the student to take the trouble to make a neat dissection, because he can find in the various museums, and notably at the College of Surgeons of England, such beautiful preparations in spirit that he prefers to study from them or from pictures rather than labor to get out the details for himself. If this is so I can only regret that the present race of students is so short-sighted, for without a working knowledge of human anatomy I can conceive of no progress in surgery.

"But I regret to find that, in Great Britain at least, the teaching of anatomy is gradually getting more and more into the hands of professors who are anatomists but not surgeons, and that their tendency is to lay stress upon transcendental details rather than surgical relations. When these gentlemen happen to become examiners this tendency to specialize becomes very marked, and, as this applies equally to the teachers of physiology and chemistry, the unfortunate medical student becomes the victim of science (falsely so called), and sometimes develops into that marvellous being, a London B.Sc.

"But seriously, are we not overdoing the scientific

teaching of the man who has after all to get his living as a practitioner of medicine, surgery, and midwifery? When the medical curriculum was lengthened by a year, it was hoped that the additional time would be devoted to clinical work; but I fear that this is by no means always the case, for it is not uncommon for the student to take three years in passing his primary examinations, with the result that but two remain for the study of medicine and surgery. When I became a student of medicine I took to heart the advice of my teacher of physiology, William Bowman, and never allowed a day to pass without visiting the hospital; and though as a lad of sixteen I failed of course to appreciate the importance of all that I saw, yet I saw it, and I can carry my mind back now to cases seen and lessons learned in the early fifties which are of service to me at the present time. But the student is practically forbidden to enter the wards now until he has satisfied the examiners in anatomy and physiology, which he may or may not do in two years, and then there are but three years left for him to study *totam rem medicam*.

"Far be it from me to decry the modern methods of teaching medicine in the wards of our hospitals. I believe that the care taken to induct every student into the mysteries of auscultation and percussion are beyond praise; and if with some teachers treatment is regarded as of secondary importance, at least the student has the opportunity of studying the *vis medicatrix naturæ* untrammelled under one teacher, and of watching the effects of every new drug upon the human system under another. But all this takes time, and so also the elaborate manipulations of the gynæcological department, the researches of the pathological professor, and all the other teachings of the third and fourth years. And where, then, does surgery come in? Why, I consider myself fortunate if I can secure the regular attendance of candidates for a surgical diploma for the last three months, when their names are put on my list, and I subject them to rigid surgical cross-examination. But if I venture to refer to an illustrative case of last year, I find that no one present saw it or even heard of it, though at the time the whole surgical staff may have been in consultation upon it. How, I ask, is it possible for the student to see the serious surgical ailments which are not very common, such as aneurism, tumors of bone, tetanus, etc., if his attendance in the surgical wards is limited to a few months?

"And yet there has never been a time of greater activity in operative surgery, not only among hospital surgeons, but among general practitioners, who, thanks to anæsthetics and antiseptics, undertake operations of a magnitude which the hospital surgeon of the last generation would have hardly attempted. How are we to explain the apparent contradiction? In the first place, I am afraid we must allow that a great many mistakes in diagnosis are made, or, rather, that too often no attempt at diagnosis is made, but that an operation is undertaken to 'clear up the case.' That it generally does no doubt, but not always to the benefit of the patient. Then we must allow that, with unlimited time for the anæsthetic, the least skilful surgeon may hope to bring an operation to a conclusion more or less satisfactory to himself, and, if he operates under fairly favorable circumstances, for his patient also. Lastly comes the enormously increased opportunity for the publication of a success at one of the numerous mutual admiration societies and in one of the medical journals of the day. Can we wonder, then, that young surgeons whose stock in trade of professional knowledge is of the smallest, blossom rapidly into operating surgeons in some special department, and try not unsuccessfully to prove that all is fish which comes to their net?

"Still, gentlemen, the great foundations of the art and science of surgery remain undisturbed. Without a knowledge of anatomy, of pathology, and histology progress in surgery is impossible, and it is for those who hold the important positions of teachers in our great medical schools to insist upon a foundation of scientific and practical training being given to our students if they are to become the successful practitioners of the future. The growing tendency of the non-medical teachers of collateral science to regard their particular subject as the one most essential for the medical student must be restrained, and the preliminary period of medical study must be cleared of many obstructions if the student is to have the necessary time to devote to the thorough study of those strictly medical subjects which will fit him to be a sound, practical and at the same time scientific physician and surgeon."

Discussion on Appendicitis. — A discussion then followed on appendicitis, led by DR. G. E. ARMSTRONG, of Montreal. It consisted of the report of 517 cases seen in the leading Montreal hospitals. It was found to be most common between the ages of twenty and thirty, and occurred twice as often in males as in females. Discussing the etiology of the question, the speaker said he could throw little light upon it, but he thought anything that removed the epithelial lining from the mucous membrane of the appendix, allowing germs to get in and do the work, was the starting-point in most cases. A stercoral ulcer might form, the healing of which caused contraction of the appendix and tended to prevent egress of material from it, and thus endangered the patient's life. The doctor handed around specimens of constrictured appendices for examination. In the total number of cases reported, the average mortality was 12.8 per cent.; but from 1853 to 1890, before operation was done—that is, in pre-operative days—the mortality was 23.8 per cent. Of the 517 cases, 389 were operated on and 128 treated without operation. In this latter list the mortality was 3.12. Of 319, 81 were interval cases, in which there was not one death. Of 305 operated on in the acute stage, 63 died. The great point in treatment was to anticipate the severer forms resulting in septic peritonitis. This, the essayist held, was accomplished by early surgical interference. Even fulminating attacks were preceded by mild attacks, in which the operation would be successful. The question when to operate was of great importance. There were two groups of cases: one, very mild, where the question scarcely arises; and the other, where there was a difference of opinion, and it was in this latter class that the judgment and experience of the surgeon were called into play to the fullest extent. Operation in the interval was safe. During the acute attack symptoms were unreliable. One must consider them all carefully, but the time did arise when only a bold surgeon would dare to wait and a cautious surgeon would dare to operate. The essayist said he had seen rapidly fatal cases follow too soon getting up, too early moving around after a mild attack, and he had seen one case of rupture follow a dose of castor oil. His rule was to advise operation at the end of twenty-four or thirty-six hours if the patient was not improving. In cases of general septic peritonitis, in which there was paresis of the walls of the intestine, he was in the habit of turning the whole intestine out of the cavity before returning any. In draining these cases he used three tubes—one in the pelvis and one in each loin. In treating the disease in the abscess stage, most experienced operators were opposed to breaking down adhesions and removing the appendix. The wisdom of that course might be questioned. He had got better results by removing the whole abscess as far as possible. If this was not done,

a secondary abscess might go undiscovered and lead to the loss of the patient's life. Thorough removal, too, of all pus, and breaking down material, lessened the chances of septic infections through the mesenteric veins and liver. In such cases he believed in surrounding the sides of the abscess very thoroughly with gauzes, sponges, etc.

Dr. Ward Cousins, of Southsea, England, in discussing Dr. Armstrong's paper on appendicitis, referred to it in very complimentary terms. He said very great care should be exercised as to the time of operation. The great question was when to operate. He did not rely on statistics, as each case must be treated individually. If symptoms are quiescent or subsiding, one should not operate. In such case the pain would be less severe, the temperature falls, the abdominal distention subsided, and the tenderness lessened. If the symptoms were increasing and very severe, operation was called for. Rapid pulse, anxious face, great distention, and induration or fluctuation would certainly indicate the necessity of operation. The induration did not, in his opinion, indicate the direction in which the appendix lies. Fulminating cases usually present all the symptoms of general peritonitis, but the disease is usually localized to the cæcum. In operating he preferred an oblique incision, as it gives a better view of the abdominal cavity and is closer to disease. He uses an electric light to enable him the better to examine the abscess, and never uses metal retractors. He prefers instead a couple of ligatures in either wall of the incision. When he reaches the abscess he drains out what pus will flow, and then wipes out the cavity. He never irrigates, and considers it imperative to be as gentle as possible in all manipulations. If the bowel is in the way, he wraps it carefully around with sponges and moves it aside. He does not use drainage tubes except when absolutely necessary, as he is afraid of them, and then usually only one large one in the groin. The surgeons of Great Britain were very chary of the surgical treatment of appendicitis. He felt that the American surgeons had stimulated them to earlier operation, and had helped them to overcome their tendency to procrastination.

Dr. Ball, of Dublin, said the number of cases of appendicitis in which he had operated could be expressed in two figures; that he had not operated so often as he might have done. Cases of this disease divided themselves into four classes. About three of them there was little difficulty. The first was where peritonitis suddenly occurred; the second embraced those in which abscess had definitely formed; and the third sort was where the patient led a miserable life by reason of repeated attacks, where operation in the interval was so safe. But it was in those cases of first attack, in which the symptoms did not enable us to form any accurate opinion as to what extent the disease had spread, that difficulty was met with. If a patient was not improving by the third day it was his rule to operate.

Dr. Jordan, of Birmingham, said that real appendicitis, strictly speaking, was a disease confined to the appendix, and when this was the case there were two sorts: First, those simple cases which got well; and second, those in which the appendix slowly distended with irritating fluid charged with organisms, which fluid made its way through into the peritoneal cavity and gave rise to other forms of the disease with complications. In such cases the physicians and surgeons should see the case together. Too much stress, he thought, had been laid on McBurney's point. Early diagnosis was very important.

Dr. Vander Veer, of Albany, N. Y., in discussing this question, said he thought that possibly the British surgeons might think the American surgeons were rather too eager to operate.

Dr. W. H. Hinckson, of Montreal, said that statistics could not be depended upon. He thought in no case should one operate to establish a diagnosis. The question of appendicitis was one that concerned the physician as well as the surgeon. They should go hand in hand in the study of the case. As far as possible he liked to get along without operation. He could call to mind at least twenty-seven cases in which he had recommended against operation, and all the subjects got well. He did not operate in more than one in ten, and he did not regret not having operated in the other nine. In one case referred to him, in which there had been three or four attacks induced apparently by overindulgence in cabbage, he recommended the patient to stop eating cabbage rather than submit to an operation. It was claimed that the operation was without danger. That was not the case. He had known instances of death to occur by reason of operation.

Ventral and Umbilical Hernia in the Same Patient was the title of a paper by Dr. A. E. Garrow of Montreal. He said cases of umbilical and epigastric hernia, having separate sacs but common coverings, for which radical cure was successfully carried out, are evidently rare, or at least not frequently recognized and reported. After carefully looking over the literature at his disposal he had found but one case reported within the last twelve years, namely, one by Ochner, of Chicago, in which radical cure was performed for a small supra-umbilical and a large umbilical hernia. Double umbilical herniæ, with separate sacs, and multiple ventral herniæ, the result of repeated laparotomies, are not uncommon at the present day. Marcy in his work on the "Anatomy and Surgical Treatment of Hernia" says of supra-umbilical hernia: "It is not rare to find examples of ventral hernia, in the middle line above the umbilicus; these, so far as I have had the means of observation, are small in size, oftentimes giving little or no discomfort; occasionally they interfere with the process of digestion, causing nausea, flatulency, and pain." In the case under consideration, the contents of the supra-umbilical protrusion consisted of large and small intestine, cæcum with appendix, and omentum, the latter being spread out so as to form a more or less complete sac; it was adherent, and could be reduced only with difficulty. The umbilical hernia, on the other hand, was small, sausage shaped, and contained but a single loop of small intestine, which was not adherent and was very readily reduced.

This case at least clearly supports the view that large irreducible herniæ may escape elsewhere than through the umbilical opening. Within the last two months I have had an opportunity of examining two cases of herniæ occurring in women past middle age in which the neck lay some distance above the umbilicus. The explanation of the few cases reported may be due to the impossibility of diagnosing such a condition previous to operation, and that surgeons are comparatively seldom called upon to give radical relief for hernia in this situation unless strangulation has occurred, because the subjects of such herniæ are usually well advanced in years, obese, frequently suffering from bronchial, renal, or cardiac disease; in short, poor patients for any operative interference, particularly a prolonged laparotomy. Besides, many of them are made comfortable by wearing some form of abdominal support. The danger in suitable cases in operating for such herniæ would not seem to be much greater than that entailed in a modern laparotomy, and the important lesson learned by the writer is that, since in such cases it is impossible to recognize the double protrusion before incision, after opening the main sac and replacing the contents within the abdominal cavity a careful search from within should

be made, to ascertain whether any other hernia exists before proceeding to remove the adipose tissue mapped out at the beginning of the operation.

W. J——, a colored female, aged forty-five, entered the Royal Victoria Hospital December 10, 1896, complaining of an abdominal tumor and asking for radical relief. Patient was married twenty-one years ago; within three years she had born three children. Some months after the birth of the third child a small lump made its appearance about one inch above the umbilicus; this lump gradually increased in size until three years ago, when it was about one-half its present dimensions, but since then it had grown rapidly. Excepting transient attacks of abdominal pain which she attributed to wind in the bowels, and some dragging-down pains, relieved by assuming the recumbent position, she had suffered but little until the last year. During the last twelve months, however, disturbances of digestion had been persistent; besides, the abdominal pains and dragging-down sensations already referred to had become much aggravated, and though benefited by rest in bed had never been entirely absent. Various abdominal pads and trusses were tried in turn, but utterly failed to give relief, in fact aggravated her symptom. Patient has had repeated attacks of what she called low fever at her home in Jamaica, also muscular rheumatism and sciatica. Examination showed a large tumor projecting from the mid-abdominal region, irregularly hemispherical, freely movable, soft and doughy in some parts but tense and elastic in others, irreducible, distinctly lobulated, somewhat tender to palpation, which elicited gurgling sounds. The note was tympanitic in some places, in others dull. The navel was at the lower left-hand side partially concealed by the overhanging mass, and the skin immediately surrounding it was superficially ulcerated, evidently from the friction of her clothes. The tissue above this part are very thin, so that the outline of the contents could be readily made out. Umbilical hernia was diagnosed because the neck of the protrusion seemed to occupy the umbilical opening.

The essayist then proceeded to describe the operation, which was performed on December 14, 1896. The incision was elliptical and was made over the most prominent part of the tumor. Much difficulty was experienced in separating the entangled structures contained in the tumors and its coats, and on raising the mass, which had been ligatured preparatory to removing it with the knife, a gurgling sound was heard, which led the operator to dissect toward the middle line with the result of finding that the mass consisted of two sacs. The peritoneum was found in both herniæ adherent to the surrounding fibrous rings and was dissected away from the margin a full inch. Each opening was then sutured in turn and separately, the skin wound closed, and the ordinary antiseptic dressing applied. The patient made a good recovery from the operation. She was kept in bed for seven weeks, all precautions being taken to keep the openings closed by strips of adhesive plaster drawing the skin from the opposite side of the abdomen. Photographs were then distributed showing the result six months later.

Traumatic Aneurism of the Internal Maxillar Treated by Ligature of the Common Carotid.—Dr. H. Langley Browne read a paper on this subject. James Pearsall, aged thirty-two, married, boatman by occupation, was admitted to the hospital at West Bromwich, March 12, 1897, suffering from a lacerated wound of the scalp, punctured wound of the right cheek, and concussion of the brain, his injuries arising from a kick of a horse. The patient was semi-conscious on admission and suffering from shock. He was bleeding profusely from the cheek, ear, nose, and scalp. The right side of the face was much swollen, the right eye was completely closed, and the swelling extended about half-way down the neck.

On examination the lower jaw was found fractured on the left side close to the symphysis, and on the right side through the neck of the jaw. Crepitus was also detected over the right malar bone. The temperature rose to 100.2° F. next evening, but then fell to normal, at which it remained till the 20th, when it registered 101.8° F. in the evening. The evening temperature continued to rise till on the 25th it stood at 104.6° F. The patient then took thirty minims of Warburg's tincture, and the temperature fell to 98.2° F.

During the next seven days the swelling slightly decreased, and on April 5th the temperature again rose to 101.2° F., and on the 9th fluctuation was detected in the neck. An incision was made in the neck and six ounces of pus evacuated. The patient was much relieved, the swelling did not quite subside, and on the 13th a copious hemorrhage from the incision in the neck took place. This was controlled and the wound stuffed with iodoform gauze. The swelling now increased, and on the 15th distinct pulsation was felt over the right cheek. On examining the mouth the soft palate was found greatly depressed on the right side and congested, and pulsation was easily felt.

On the 24th he had a slight hemorrhage from the mouth, and again on the 26th a copious hemorrhage took place from the mouth, and Dr. Browne then decided to ligate the carotid. This was done on the 26th, and the patient was easy and restful. On the 29th he passed fæces involuntarily, but since that time he has had perfect control. He was discharged cured on May 24th, and has since reported himself weekly at the hospital.

Intussusception of the Vermiform Appendix and Cæcum was the title of a paper by Theodore A. McGraw, of Detroit, Mich. The speaker reported the case of a boy, seven years old, who suffered from a form of intussusception which the speaker believed was unique and threw a light on the pathology of the affection. The salient points of the history, which up to the time of operation covered upward of four months, were as follows: An attack of cholera morbus was followed by only partial recovery, and for a period of some weeks attacks of diarrhœa and very severe pain occurring in paroxysms were the prominent symptoms. There was no fever during this period, and for a few days at a time the boy appeared to enjoy fair health. There was occasionally some traces of blood in the stools. The attacks of pain became more frequent and severe as time went on, until it was deemed advisable to make an exploratory incision. No tumor could be felt in the rectum nor in the iliac fossa. He referred his pain to the epigastric region. There was but little tenderness and no tympanitis. His tongue was clean and his appetite good. The day before the operation the temperature rose to 100.2° F. An exact diagnosis was impossible. Immediately on opening the peritoneal cavity the transverse colon presented itself intensely red, highly inflamed, and coated with lymph. The ascending colon had a meso-colon of such length that he was able to draw it and the cæcum with ease through the opening made above the navel. The cæcum and appendix were invaginated and made a tumor within the gut, which could be felt through the walls of the colon, about the size of a walnut. The ileum was not invaginated. The speaker then continued that he thought it better surgery to remove the invaginated portion rather than merely to replace it, as he felt the affected part would most likely return to the old condition; in other words, that the affection would be almost sure to recur. He therefore removed the diseased part completely and united carefully the cut edges with catgut sutures,

one for the mucous and one for the serous surfaces. The child made a splendid recovery. He had no more attacks of pain and gained in health.

The peculiar point of the case was the occurrence of the invagination at the extreme end of the cæcum, and not in its continuity or at the ileo-cæcal valve. In all other cases which had been reported the ileo-cæcal valve formed the apex of the tumor in the cæcum.

An Analysis of One Thousand Cases of Lateral Curvature of the Spine Treated by Posture and Exercise Exclusively (without Mechanical Supports.—Dr. Bernard Roth, Brighton, Eng., presented a paper on this subject. This paper relates to 1,000 consecutive cases of scoliosis which have been under the author's treatment in private practice from June 27, 1885, to November 24, 1892, and are subsequent to a series of 200 cases reported at the annual meeting of the British Medical Association in 1885. The whole of these 1,000 cases have been treated by the methods described in the author's book, "The Treatment of Lateral Curvature of the Spine," 1889. The author hopes by the publication of this series to convince a larger proportion of the medical profession of the superiority of, and the much more rapid results obtained by, his method at all stages and at all ages than by the old treatment of lateral curvature by spinal supports or other mechanical means.

Sex: The 1,000 cases consisted of 122 males and 878 females. Messrs. Bradford and Lovett in their "Orthopædic Surgery," 1890, have collected 2,340 cases, of which 363 were males and 1,979 females; that is, a percentage of 15.5 males to 84.5 females, which is to be compared with the author's percentages of 12.2 males to 87.8 females.

Age when brought to the author and age when the deformity of the spine was first noticed: The average age of the 1,000 cases is 12.32 years for the commencement of the deformity, and 15.65 years for the age at which they came under treatment; 897 cases (*i.e.*, 89.7 per cent.) commenced to develop lateral curvature between the ages of five and seventeen years, and more than half by 594 between the ages of ten and fifteen years.

Causes of lateral curvature of the spine: In 231 cases no assignable cause of the deformity could be found, while of the remaining 769 cases 297 were hereditary; 203 were due to rapid growth; 176 were described as delicate; 59 followed acute specific fevers, scarlet fever, whooping-cough, measles, typhoid fever, etc.; 41 were attributed to lung diseases; 27 were born in tropics; 24 had a neurotic origin; 14 were attributed to overstudy, violin playing, etc.; 11 were attributed to premature birth; 10 were attributed to eye affections; 8 were twins; 5 were children of elderly parents; 11 were attributed to miscellaneous causes (as being very tall, above 6 feet, 3 cases; to rickets, 2 cases, etc.).

The very small percentage of cases which were attributed to rickets is due to the fact that almost invariably patients came from the middle and wealthy classes and included no hospital patients.

Description of the different forms of the lateral curvature of the spine: The 1,000 cases divide readily in six classes:

(*a*) With whole convexity to left—523, or 52.3 per cent.

(*b*) With dorsal (upper) convexity to the right and lumbar (lower) convexity to the left—329, or 32.9 per cent.

(*c*) With whole convexity to right—72, or 7.2 per cent.

(*d*) With dorsal (upper) convexity to the left and lumbar (lower) convexity to the right—45 or 4.5 per cent.

(*e*) With triple curvature, highest and lowest curves being convex to the left and middle curve convex to the right—28, or 2.8 per cent.

(*f*) With triple curvature, highest and lowest curves being convex to the right and middle curve convex to the left—3, or 0.3 per cent.

Amount of osseous or incurable deformity of the ribs and vertebræ: If osseous deformity is present, to that extent the case is incurable and no patient has ever been exhibited at any recognized medical society with slight or severe osseous deformity before treatment and shown again after treatment with this osseous deformity corrected. The method of scoliosiometry which the author has employed for many years and which he first published in the *British Medical Journal* of October 27, 1888, is still the simplest and most rapid method of recording the degree of osseous deformity in lateral curvature. The amount or degree of osseous deformity is classified as extreme, severe, moderate, and a trace. If the ribs posteriorly and the erectores spinæ are perfectly symmetrical when the trunk is well flexed, absence of osseous deformity is diagnosed. Of the 523 cases of deformity (*a*) 117 cases had only moderate deformity of the lumbar vertebræ and 76 cases had a trace of osseous deformity of the left ribs posteriorly and moderate osseous deformity of the lumbar vertebræ. Of the 329 cases of deformity (*b*) 67 had moderate deformity of the right ribs posteriorly and of the lumbar vertebræ with convexity to the left. The 72 cases of deformity (*c*) had 14 with moderate osseous deformation of the right ribs posteriorly and of the lumbar vertebræ. The 45 cases of deformity (*d*) had 10 with moderate osseous deformity of the lumbar vertebræ; while the 28 cases of deformity (*e*) and 3 cases of deformity (*f*) all had more or less osseous deformation of the ribs posteriorly and of the lumbar vertebræ: of course when osseous deformity of the ribs posteriorly is indicated, osseous deformity of the dorsal vertebræ is implied. Only 79 cases out of the whole 1,000 were without definite osseous deformity.

Pain or backache; 476 cases, viz. 47.6 per cent., had more or less backache, including 11 with extreme pain, 230 with severe pain, 87 with moderate pain, and 148 with slight pain.

Flatfoot: The author was one of the first surgeons to point out the extremely frequent association of flatfoot with lateral curvature of the spine (see *British Medical Journal* of May 13, 1882). Out of these 1,000 cases, 565, viz., 56.5 per cent., had more or less well marked flatfoot, and 256 cases in addition had a trace of flatfoot which perhaps some surgeons would not accept as such.

Previous, *i.e.*, unsuccessful, treatment of the 1,000 cases: Omitting treatment by ordinary or special gymnastics, suspension by the head and the innumerable forms of shoulderstraps, etc., 202 cases had been treated by means of spinal supports, including 104 cases by steel supports and 98 by other forms of spinal supports. Of these many had worn supports for several years; thus 24 had worn them for 1 year, 25 for 2 years, 19 for 3 years, and so on, including cases in which spinal supports had been worn for 10, 11, 12, 16, 20, 25, and even 40 years.

Duration of the author's personal treatment: The average course consisted of three months' daily treatment or 72 visits; 634 cases underwent that amount. Early cases of lateral curvature with little or no osseous deformity of the vertebræ to the number of 265 made each from 24 to 48 daily visits; 28 adult male cases have been treated on 36 alternate days or by weekly visits. The remaining 73 cases, with 6 to 18 daily visits, and with 81 to 216 daily visits, have been exceptional patients, in whose cases the treatment has either been interrupted too soon or from intercurrent illness unduly prolonged.

Result of author's treatment: As osseous deformity of the vertebræ even to the slightest extent is to that extent incurable, the author has not ventured to label any case as "cured," although probably most surgeons would have employed that term instead of "much improved." By "much improved" the author describes the best possible result that he was able to prognosticate when the patient was first examined; that is, a strong and much straighter spine where the most improved posture possible has become a more or less habitual one, with disappearance of backache, with improvement in the general health where this has been failing, and finally with arrest of further increase of the osseous, *i.e.*, incurable deformity of the ribs and vertebræ. There were 869 cases much improved, and 75 cases improved. By "improved" the author distinguishes those cases in which arrest of the further increase of the osseous deformity has been effected, but in which pain has still persisted more or less or in which the patients have not held themselves so well as they ought to have done. Fifty-six cases were more or less failures, including 47 which were apparently successful at first but then relapsed, and 9 which were not improved from the very first. Most of these 5.6 per cent. failures have been due to want of intelligence or perseverance in the several patients. The most successful of the author's cases and those which gave least trouble were young men anxious to become officers in the army and who ran some risk of being rejected as physically unfit, and young women engaged to be married. Of the "much improved" and "improved" cases, 207 were confirmed by examination during the first three years following the completion of their treatment under the author's personal care. Some were reported as continuing straight and well ten years after.

Four hundred and twenty-nine cases were sent direct to the author by two hundred and two medical men, to whom he conveys his thanks.

(To be Continued.)

THE NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, April 28, 1897.

JOHN SLADE ELY, M.D., PRESIDENT.

Disease of the Coronary Arteries with Red Infarction of Myocardium.—DR. JOHN H. LARKIN presented specimens taken from a woman, forty years of age, a chronic alcoholic, who had had several attacks of acute rheumatism. Four months ago she became lame and the ankles were much swollen, the breath was short, and there was slight and gradually increasing cough. She also complained of weakness, headache, and some gastric pain. Later there was a good deal of blood-tinged expectoration. Five weeks ago she entered the hospital. The heart was enlarged, and there was a systolic murmur at the apex and one at the base, with a systolic thrill. There were cough and profuse frothy expectoration. No tubercle bacilli were found in it. There was occasional vomiting for a week or two before death, but no elevation of temperature. The urine had a specific gravity of between 1.020 and 1.030, and contained a trace of albumin but no casts. At the autopsy the lungs showed brown induration, with multiple hemorrhagic infarcts. The liver was "nutmeg." The spleen contained fresh and old infarcts. The kidneys showed the lesions of chronic diffuse nephritis and also old infarcts. The coronary artery was occluded by an embolism. On the inner surface of the endocardium, both on the papillary muscle and on the mitral valve, were numerous vegetations, some of which could be seen hanging by thread-like processes. One of these vegetations was removed from the mitral valve, and also a small white thrombus from the coronary artery. Microscopical examination proved these to be identical in structure. At the apex of the right ventricle was a large globular thrombus filled with a milky fluid. Dr. Norris had made cultures from the thrombi, and also from the heart muscle, with negative result, even after several weeks. In the region supplied by the anterior coronary artery—the tip of the left ventricle and a portion of the right ventricle—was a distinct area of softening in the cardiac muscle. There was no interstitial myocarditis. The heart was otherwise fairly normal, except for the increase in size, due rather to dilatation of the left ventricle than to hypertrophy with dilatation. Sections of the cardiac muscle were exhibited under the microscope. They showed very well the large effusion of blood into the heart muscle, displacing the muscular fibres of the heart. There was also some compression atrophy of the heart muscle fibres in the immediate vicinity of the hemorrhage.

Atrophy of the Pancreas with Replacement by Fat.—Dr. Larkin then presented sections of the pancreas from a woman, fifty years of age, who had been admitted to Bellevue Hospital in November, 1896. She was addicted to the use of beer, tobacco, and morphine. She said that she had been well up to one month previous. Then she had chills and headache, followed by fever, thirst, and weakness. On admission there was slight cough, with dyspnœa on exertion. She passed large quantities of urine. The bowels were constipated and the appetite was fair. Thirst was marked, the mouth was dry, and the tongue cracked. The temperature was 103° F.; pulse, 112; respirations, 36. Physical examination showed the chest to be barrel shaped; there was diminished and prolonged low-pitched expiration, and a few subcrepitant râles were heard over the back. The size of the heart was normal, but its action was very irregular in force and frequency. No murmur could be heard. The liver was not palpable. The spleen was normal. The urine had a specific gravity of 1.012, and contained a trace of albumin and some granular casts. One drop of the urine gave a pronounced reaction with Fehling's test at one time, but not on other examinations. At the autopsy the brain was "wet," there was moderate atheroma of the arteries of the base, the anterior portion of the pia mater was lustreless. The heart was very pale and exceedingly fatty; there were no valvular lesions. The lungs were emphysematous and œdematous posteriorly at the base. The spleen was hard, large, and congested. There was a large nutmeg liver. The kidneys were of normal size, the cortex was pale, and the markings were fairly distinct. Connected with the left kidney was a tumor, the size of a small orange, containing a viscid fluid. At the edge of this tumor was a blood-vessel apparently connected with the renal artery. Cultures made from the viscid contents of the tumor proved negative as regards tubercle bacilli, etc. The pancreas measured transversely about two centimetres. It was much diminished in size, the greater portion of the pancreatic tissue being replaced by fat, which appeared as large yellowish areas shutting off little islands of pancreatic tissue. The small tumor was a telangiectatic sarcoma.

THE PRESIDENT said that Dr. Larkin, in speaking of the structure of the thrombus in the coronary artery being identical with that of the vegetation on the mitral valve, had expressed the opinion that the occluding mass was an embolus. To this he could hardly agree, as it seemed to him the mechanical difficulties would be enormous, owing to the course of the blood current and the peculiar manner in which the coronary arteries are given off behind the mitral valve and at right angles to the course of the blood in the aorta. On *a priori* grounds merely it seemed to him that em-

bolism of the coronary artery should be extremely rare. As to the occurrence of sudden death in disease and occlusion of the coronary artery, in his opinion it would make a very great difference which coronary artery was occluded as to whether or not sudden death occurred. Why should the heart suddenly stop beating simply because one of the branches of the coronary artery going to the apex had become occluded? An occlusion of the branch running upon the heart in the auriculo-ventricular ring might cause sudden death, because that is the situation of the intrinsic cardiac ganglia. It seemed, therefore, that for absolute and sudden stoppage of the heart, the determining factor, when there is no rupture, must be the degeneration, impairment, or cessation of the function of these intrinsic cardiac ganglia. Experiments apparently confirming this view had been published. On the other hand, if the circulation of the horizontal branch were left intact, stoppage of the branch going to the apex might occur without seriously affecting the intrinsic cardiac ganglia.

Dr. James Ewing said that last summer a man, forty or fifty years of age, had come under observation, who was addicted to the use of enormous amounts of morphine hypodermically. Shortly after one excessively large injection he died. The autopsy showed a well-developed adipose layer all over the body, and a large amount of perirenal and retroperitoneal fat. With some difficulty the pancreas was found in this mass of fat. On section it was found that the organ was the seat of fatty replacement. The remaining islands of pancreatic tissue were apparently normal.

The society then adjourned.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending August 28, 1897:

	Cases.	Deaths.
Tuberculosis	137	68
Typhoid fever	26	12
Scarlet fever	68	3
Cerebro-spinal meningitis	1	1
Measles	42	4
Diphtheria	124	18
Laryngeal diphtheria (croup)	3	2
Chicken-pox	1	—
Pertussis	6	4

The Baths at Harrogate.—At this well-known spa, in Yorkshire, England, probably the most magnificent baths in the world have just been completed. These erections cost $600,000, and were opened to the public on July 21st. In addition to an immense pump room, ladies and gentlemen's baths, winter garden, Turkish and Russian baths, is an inhalation room, containing a sulphur-water fountain, giving off a fine spray which is inhaled by the occupants of the apartment; there is also a "pulverization room," where medicated water can be applied to the throat, eyes, etc. Among the other varieties of baths may be mentioned several kind of douche, slipper, and needle baths.

Microbe Ragout. — Parisians have been greatly alarmed by learning through the daily press that a robbery had taken place at the Aubervilliers Hospital, which is specially devoted to contagious diseases. A number of rabbits inoculated for some researches of M. Roger have been stolen, and they had been inoculated with diphtheria, tetanus, typhus, cholera, etc. As it is probable that the thieves sold the rabbits to dealers, every one who supped off rabbit that evening is consumed with a horrible fear of having caught some infection. Interviews with Dr. Roux and other authorities have been published and instructions have been given to the octroi officials to stop the entry of such rabbits, their carcasses being easily recognized by having been shaved for the purpose of inoculation.

The Dangers of Chlorate of Potassium.—A notion is prevalent among the public that chlorate of potassium is a remedy which may be safely indulged in to an unlimited extent, but it is high time that this dangerous error should be exposed. Therapeutists are well aware that even in comparatively moderate doses chlorate of potassium is a very active drug, producing a marked effect upon the blood, which it turns brown, and leading in large doses to cardiac paralysis, albuminuria, and death. Instances of this sort are not very rare, and but a few days ago a young man at Morpeth died from sucking pellets of the drug with the object of preparing himself to sing. He absorbed altogether two-thirds of an ounce, causing death from syncope. Even in what are considered safe doses chlorate of potassium often gives rise to great mental and physical depression, insomnia, and various other disturbances of the human economy.—*Medical Press and Circular.*

Reichmann's Syndrome.—In a critical review of recent works upon continued hydrochloric hypersecretion, Dr. Jean Ch. Roux (*Gazette des Hôpitaux*, May 29, 1897), after describing the morbid symptoms frequently observed in dyspeptics, concludes: 1. It is better to speak of the syndrome of Reichmann than of the disease of Reichmann. 2. It is an exaggeration to look upon the syndrome as being always the clinical expression of motor insufficiency of the stomach (Schreiber), due almost exclusively to an incomplete organic stenosis, pyloric or subpyloric (Hayem). 3. In most instances we should admit an exaggerated secretory excitability of the stomach's mucous membrane, the patients being hyperchlorhydrics before the appearance of Reichmann's syndrome. 4. The syndrome should be admitted as existing only when, in the course of a test meal carried out after washing out the stomach, a quantity of hydrochloric acid, free or combined, is discovered in much larger quantities than normal. The examination of the fluid obtained in the morning while fasting is not, in the author's opinion, sufficient to characterize Reichmann's syndrome. 5. The syndrome is encountered in gastric dilatation of passing or lasting nature, according as there exist or not material lesions of the stomach, and particularly in the pyloric region (these lesions may be ulcer in condition of activity, chronic ulcer, cicatrized ulcer, or cancer). It thus results that Reichmann's syndrome may be itself of short or permanent duration. 6. There are intermediary forms from simple to continued hyperchlorhydria. 7. At all events, we must admit that stasis plays an important rôle in the chain of symptoms, if it does not in itself suffice to create the syndrome. It is certain that it suffices to make it disappear in order to bring about a considerable amelioration and even complete cure. We have here an indication of the first order for our medical and surgical therapy.

Dispensary Abuse.—We are glad to note that the failure of the governor to sign the bill regulating dispensary practice, and doing away with many of its present evils, has not thrown cold water upon the efforts of the advocates of the bill. On the contrary, it has acted as a decided stimulant to the fight against dispensary abuse. Medical societies are exerting their power against it; medical periodicals have dis-

cussed it *pro* and *con* and from every conceivable standpoint. We are pleased to see that the crusade has become so general and strong, and that this strength presages the ultimate doing away with, to a degree at least, of a practice which is not only sapping the profession of its income but its dignity.—*Albany Medical Annals.*

The Seat of Lumbago.—Mr. Jonathan Hutchinson, in the April number of *Archives of Surgery*, says concerning lumbago: "It may perhaps seem to savor of the love of contradiction if I assert that the pain in lumbago is not in the lumbar muscles nor indeed in the loins at all. Yet I feel sure that such is the case. I have asked hundreds of its subjects to put the hand over the exact site of the pain, and with the invariable result that the sacral region is the part indicated. If we wish to use this word with precision we should understand it to denote a liability to pain on movement across the sacrum or in the sacro-iliac synchondroses."

Violent Remedies.—Professor Brouardel, in a recent lecture, related the following case: A man had a pharyngeal abscess, so deeply seated that his medical attendant was afraid to meddle with it. One night a burglar broke into the house, and on the sick man calling for help tried to throttle him. The abscess burst, deluging th burglar with pus and causing him to beat a rapid retreat His intended victim experienced instant relief and made a rapid recovery.

A Serum Jag Cure.—A physician on the Pacific coast claims to have discovered a cure for drunkenness by inoculation of horse blood. The substance which he gains by injecting alcohol into the blood of a horse he calls equisin. Alcohol is introduced into the horse and the blood drawn off into a sterilized vessel, in which it is mixed with chloral to influence the clot. After settling for twenty-four hours it is subjected to a freezing process, and then shaken for half an hour. The result is a thin, somewhat sticky fluid.

A Celebrated Quack.—A writer in the *Illustrated London News* narrates some very curious incidents in connection with the practice of medicine in England. Some sixty years ago Mr. St. John Long was, although unqualified, practising in Harley Street, and had made for himself a great reputation, particularly for his treatment of consumption. His method, shortly stated, was in cases of internal disease to cure the malady by causing an external wound. The effects of this treatment were always painful and often shocking to behold. A Dublin lady came up to London to consult him concerning the health of her two daughters. The younger was far gone in consumption; the elder perfectly well. What had happened to her sister naturally alarmed her, however, and Long undertook to prevent her falling a victim to the same disease. He applied his remedies, which gave her intense agony and made her very ill, and on the tenth day Brodie was called in, but too late, for the patient died. The body of the poor girl was exhumed and examined by a committee of doctors. It was shown that there was nothing the matter with her save a wound in the back, apparently produced by fire, though the mode of inflicting it could not be discovered. That was Mr. Long's secret. At the inquest medical testimony was unanimous against him, but he had a cloud of witnesses, male and female, most of them his patients, who gave evidence in his favor. In the end the coroner's jury returned a verdict of manslaughter, which was received in a crowded court with cries of "Shame! shame!" On his trial at the Old Bailey he was found guilty, but escaped on paying a fine of £25c to the king. Long was subsequently tried a second time for pursuing the same treatment with fatal results, but was acquitted. He acknowledged an income of £12,000 a year. There is a monument to him in Kensal Green cemetery, erected by his former patients.

The Plague in India.—In India, coexistent with and indeed tracing its source from the plague, there has been an ominous and increasing feeling of unrest among a portion of the native population. The Hindoos above all else are sensitive to any slur or seeming slur on their religion; their caste prejudices are unconquerable, and unfortunately some of the sanitary measures necessary for checking the inroads of the pestilence have clashed with religious and political sentiments. *The Lancet* of July 24th, in an article on the plague and its literature, does not see in the late riots and murders at Poonah much cause for uneasiness, although admitting that there is considerable local disaffection. At any rate the measures taken for the suppression of the plague, however obnoxious they may have been to the Hindoos, have attained their object with great success, and from all accounts the worst appears to be over. Among the many official and medical reports and the vast mass of literature bearing on the plague in all its phases, the results of the commission under Professor Koch, which have just been published, will probably be of the widest general interest. *The Lancet* says that Koch has found that the plague bacillus, outside the human body or those of certain animals, has very brief vitality. The duration of the life of the bacillus was found to be from eight to ten days at most. The bacilli do not develop without the influence of oxygen. Experiments on animals showed various results. Rats were found to be in the highest degree susceptible, and to be the chief medium for spreading the plague germs and communicating them to human beings. The commission observed only isolated cases of illness among people camping in the open, while among those who had remained indoors the epidemic continued its ravages without abatement. Haffkine's system of inoculation, which was applied to fourteen hundred patients, showed undoubted protective results, although a number of patients were, it is stated, made seriously ill by the inoculations. From this and other reports we may believe that under proper sanitary arrangements the plague will soon lose its hold. This is plainly shown by the fact that those who camped in the open were comparatively free from the scourge. This disease can exist and flourish only in dirty and unsanitary surroundings.

Books Received.

While the MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will be promptly made of their receipt under this heading, it must be with the distinct understanding that its necessities are such that it cannot be considered under obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

A CASE OF PHLEGMONOUS GASTRITIS FOLLOWING ULCUS CARCINOMATOSUM OF THE PYLORUS—DILATATION, PERFORATION, AND PERITONITIS—A CLINICAL HISTORY OF FOURTEEN MONTHS WITH CHEMICAL, BACTERIOLOGICAL, AND HISTOPATHOLOGICAL STUDY.

BY JOHN C. HEMMETER, M.D., PH.D., M.D.

AND

DELANO AMES, A.B., M.D.,

LECTURER ON PATHOLOGY, ETC., [illegible]

A DISEASE which is so rarely observed that there are but fifty-six cases reported in the medical literature of the world is always interesting, especially when the patient has been studied at intervals for fourteen months, has been under the almost constant observation of the authors for the last two months of his illness, and upon whom a satisfactory autopsy has been held.

In December, 1895, our associate, Dr. Edward L. Whitney, demonstrator of clinical pathology in the Baltimore Medical College, treated the patient during a typical attack of gastric ulcer. The following note of the case, made by Dr. Whitney at the time, is a concise history of the attack, giving an account of the hæmatemesis, dorsal and epigastric pain spots, great excess of hydrochloric acid, and recovery after treatment by rest, rectal alimentation, nitrate of silver, bismuth subnitrate, and alkalies.

Dr. Edward L. Whitney's Notes of the Case.—In December, 1895, I was asked to see the colored patient, George Williams, in consultation, and made the following notes of the case: The patient is a fairly well-nourished colored man, giving a history of pain in the stomach near the pylorus for several weeks, intensified by eating. For a few days he had had occasional attacks of vomiting, the vomited matter containing fresh red blood. Physical examination showed no dilatation, no palpable tumor, exquisite tenderness over the pylorus and over the eleventh dorsal vertebra, extending slightly to the left. While no palpable tumor could be made out, there was slightly increased resistance over the pylorus.

After the double test meal employed at the Maryland General Hospital, the amount was found to be about one hundred cubic centimetres. It was clear, contained no blood, was of normal odor, showed no lactic acid, but the reaction for erythrodextrin was pronounced. The contents showed no proteids, but a large amount of starchy matter from both test meals. The total acidity was 110. There was an excess of hydrochloric acid by the Boas test.

The patient was at once put on the usual treatment for gastric ulcer: absolute rest and rectal feeding (milk, egg, whiskey, and boiled starch). Small doses of the nitrate of silver were given in the morning, dosage with alkalies after meals was kept up, and moderate doses of bismuth subnitrate were given. In two weeks the patient began to improve and in about four weeks was completely relieved of all pain as well as of other symptoms, and was able to resume his accustomed work. After this he passed from observation until he entered the Maryland General Hospital.[1]

On December 1, 1896, the negro George Williams was admitted to the Maryland General Hospital and gave the following history: Age, forty-nine years; married; family history good. No hereditary facts of importance. Is the father of nine children, all in good health. Worked in the coal-oil business for fourteen years, but for the past six years has followed the calling of a cooper.

The anamnesis: Has always been strong and healthy up to four years ago when he had an attack of influenza lasting about four weeks. This he asserts left him permanently weak.

In June, 1895, he was taken with an attack of vomiting associated with violent pains radiating from the epigastrium to the umbilicus. The vomited matter "made his teeth stand on edge." He recovered from this illness without treatment.

In December, 1895, he had a second illness during which he vomited regularly after he had taken food. At this time the pains were localized in the epigastrium, occasionally shooting back to the shoulder blades. The vomit is described as having been very bitter and acid. Sometimes he brought up very clear irritating fluid containing no food. At other times he vomited blood. He was continually constipated. (This is probably the attack during which Dr. Whitney treated him.)

After a treatment of four weeks he recovered and worked at his trade for the next seven weeks.

About the middle of February, 1896, a third attack was experienced, in all respects identical with the two previous ones except that there was more vomiting, particularly of blood, more pain, and a loss of fifteen pounds in weight in two weeks. He claims to have been jaundiced, but little importance can be attributed to this assertion, as the conjunctivæ are said to have been always pigmented and the skin of the negro permits of no judgment being formed on this question.

He improved once more and resumed work, but on November 1, 1896, the vomiting of food and blood and the pain returned. He requested admission to the hospital, November 30, 1896.

On December 1, 1896, he was given the Maryland General Hospital double test meal as follows:

At 8 A.M., one small piece of beef, scraped and boiled, 80 grams; one soft-boiled egg; boiled rice, 30 grams; milk, 250 c.c.; bread, 50 grams.

At 1 P.M., an Ewald test meal.

The advantage of this double test meal has been set forth in Hemmeter's work on "Diseases of the Stomach," p. 88.

The first meal was vomited about forty-five minutes after it had been eaten. The results of titration by Toepfer's method were as follows: Total acidity, 94; free hydrochloric acid, 34; combined hydrochloric acid, 24; acid salts and organic acids, 46; lactic acid absent by Boas' test: erythrodextrin present. No blood, bile, or tissue fragments. Small amount of

[1] On one occasion (December 4, 1895), his total acidity was 124 and some blood was contained in the tar-colored stool.

mucus. When this test meal was given there had been no hæmatemesis for ten days.

Physical examination: Heart and lungs normal. The tongue is red at edges. Urine cloudy; specific gravity, 1,024; amount in twenty-four hours varying from 320 c.c. to 600 c.c. It contains a great excess of indican and urophen but no albumin, casts, or sugar, and a high ratio of ethereal to preformed sulphates.

Several tables of detailed analyses by Dr. Whitney are appended.

December 2d.—On moderate distention with carbon dioxide a gastrectasia could be distinctly made out by simple inspection. The greater curvature was two inches below the umbilicus. A nodular thickening about two to three inches long, quite hard to the touch, could be felt at the pylorus through the emaciated abdominal walls. The liver was normal to percussion and palpation. There was no evidence of movable kidney. The patient was now fed by rectum, his stomach washed out with sodium bicarbonate, and he was subsequently treated by bismuth irrigations, according to Fleiner's method. His temperature was 97 F.; pulse, 80; respirations, 24. He had no natural stool for a period of eight days. A daily cleansing enema precedes the rectal feeding.

As the patient improved until December 11th, he was exhibited to the clinic, and the Einhorn electric diaphane was introduced. The light did not shine through the abdominal wall of the colored man as well as it did on an equally emaciated white patient; still it could be plainly seen and reached down to a point half-way between the symphysis pubis and the umbilicus.

The capacity of the stomach by Hemmeter's method[1] was twenty-three hundred cubic centimetres. As this method was originally devised to obtain graphic records of the motor function[2] a gastrogram was taken,

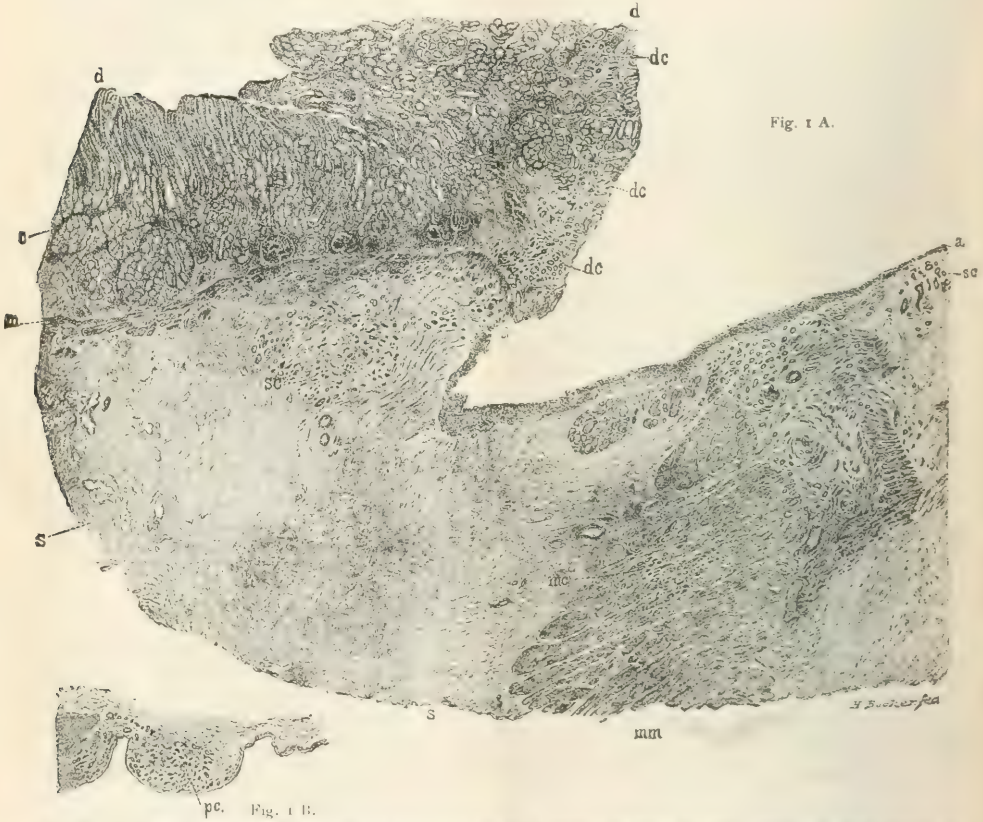

Fig. 1 A.

Fig. 1 B.

Fig. 1 A.—A section through the wall of the stomach, showing [illegible] edge and a portion [illegible] base of the ulcer. Objective, two-thirds; eyepiece, two inches. Stained with hæmatoxylon and eosin. The drawing is built up from a series of microscopic fields. Magnification, about 15 diameters.

Explanation.—*d*, Mucous membrane; *dc*, muscularis mucosæ; *s*, submucosa; *c*, base of the ulcer; *m*, muscle coat of stomach; *sc*, groups of cancer cells between the bundles of muscle fibres; *d c*, groups of cancer cells in the edge of the ulcer in the mucous membrane; *sc*, groups of cancer cells in the submucosa; *a*, necrotic membrane lining the base of the ulcer.

B.—A small nodule from the serous coat of the stomach over the base of the ulcer. Objective, two-thirds; eyepiece, two inches. Stained with hæmatoxylon and eosin. Magnification, about 15 diameters.

Explanation.—This figure gives a good idea of [illegible] the serosa. It is composed entirely of a [illegible] groups and masses of closely packed cancer cells, so closely packed that the outlines of the individual cells cannot be made out. Except for these nodular thickenings the serosa was not altered. *A*, Cancer masses in peritoneal coat.

showing that the peristalsis was not seriously impaired, and the food retention was most probably due to an insurmountable obstruction at the pylorus. In view of the clinical history of ulcer and the abnormal capacity with increased amount of hydrochloric acid, absence of lactic acid, the diagnosis of gastrectasia depending upon cicatricial stenosis of the pylorus was made very probable.

A striking symptom in this case was that for two months his temperature did not rise above 98° F. During a very evident perforation peritonitis with disappearance of liver dulness, the temperature was subnormal, standing at 97° F. At one time it sank to

[1] Loc. cit., p. 70.

[2] See New York Medical Record, June 27, 1895.

93 F. This is of interest in view of the fact that the autopsy revealed a diffuse phlegmonous gastritis, a prominent symptom of which is high fever.

Resorption from the stomach was tested by Penzoldt's and Hemmeter's methods, and found to be almost entirely lost. Bacterial cultures from the vomit resulted in prolific growths of streptococci and, what was significant, of the Oppler-Boas bacillus. There were also many other varieties of organisms, but these were the most important.

The vomit showed at times the presence of pus in traces. This was confirmed microscopically.

On account of the great irritability of the stomach, rectal feeding was almost exclusively depended upon for nourishment. The stagnation was partially prevented by careful lavage every other day. We considered the advisability of lavage in a case of this kind and concluded that the remote dangers of its use were not so grave as those of persistent vomiting and auto-intoxication. Operation, or at least an exploratory laparotomy, was suggested, but permission was refused.

On January 18, 1897, the patient's temperature suddenly fell from 98.8° to 94° F., the pulse became feeble and fluctuated between 60 and 64 per minute, respirations ranging between 14 and 20. There was occasional vomiting, or rather retching. His abdominal muscles became very hard and rigid. On percussion the normal liver dulness could not be made out. These symptoms and signs became more marked during the following days. All gastric alimentation and treatment were stopped. With these unmistakable signs of perforation, œdema of the lower extremities and uncontrollable hiccough developed. The patient died on February 1, 1897, having been in the hospital just two months.

The main features of the clinical history are as follows:

(1) The long time that the patient was under observation, from December, 1895 (Dr. Whitney), to February, 1897, but with distinct history of gastric ulcer as early as 1895.

(2) The continued presence of normal or supernormal amounts of hydrochloric acid in the stomach contents to the end.

(3) Owing to this no lactic acid, although there was a large gastrectasia.

(4) Probable development of a carcinoma from the ulcer. Tumor, progressive cachexia, and the presence of the Oppler-Boas bacillus.

(5) The presence of blood, pus, and of the pyogenic cocci in the stomach contents.

(6) The continued subnormal temperature, particularly after the

(7) Perforation.

The perforation had occurred, as will be seen later,

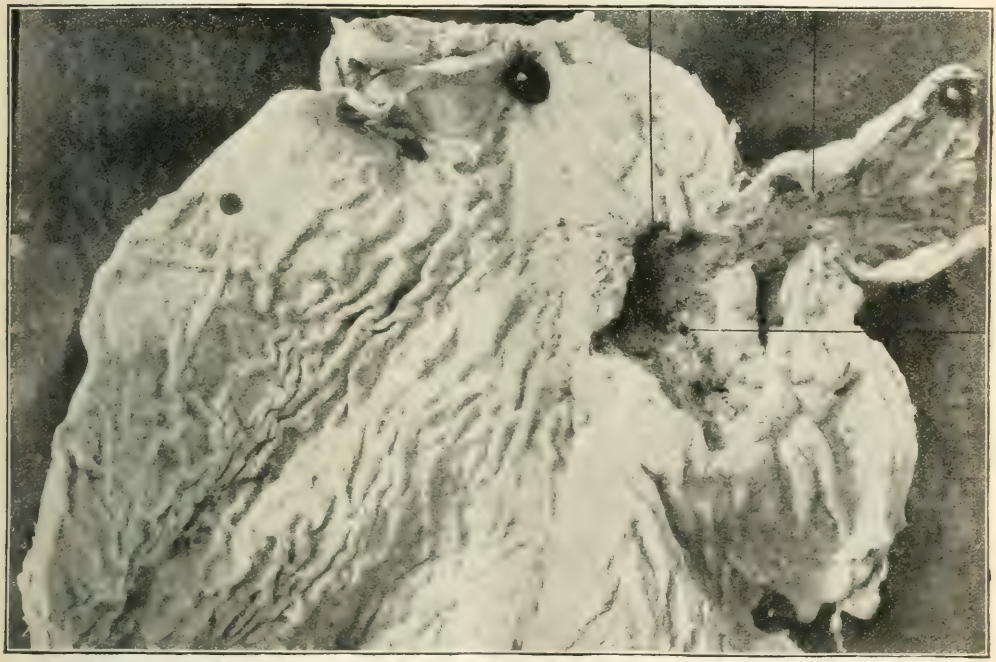

FIGURE 2.—Reproduction of a photograph of the opened stomach, showing the nearly circular ulcer, with comparatively smooth edges near the pyloric opening. The swollen, raised condition of the ulcer walls is well shown, as is also the normal, wrinkled condition of the gastric mucosa. The point where perforation occured is seen as a dark spot, to the right and a little above the centre of the ulcer. The stenosed condition of the pylorus is not shown, as the pyloric opening and the duodenum have been laid widely open. It can be seen, however, that the ulcer does not involve the duodenum. At one place a small cube of tissue has been removed.

in the floor of the ulcer, in the base and walls of which a carcinoma had developed. The stenosis of the pylorus was not absolute, a small passage, permitting with difficulty the entrance of a small lead pencil, still existing.

The Necropsy.—Section No. 124 was made twenty-four hours after death on February 2, 1897, by Dr. Delano Ames, assisted by Dr. A. A. Huntley, and the following notes were dictated at the time. The body is that of a negro, five feet eleven inches in height, and apparently fifty years old.

Muscular development is fairly good, but nutrition has been much impaired. Rigor mortis is well marked.

The usual post-mortem lividity is found in those dependent parts that were not in contact with the bed, and is more noticeable than usual in the negro, because of the light color of the subject.

There is a slight, dark, fluid discharge from the mouth. The tissues of the right hand and of the chest

are quite œdematous, but other than this there are no external signs of note.

Abdomen. Upon making the usual primary incision the muscles of the thorax and abdomen are seen to be of the normal color. The subcutaneous fat is almost entirely absent. On opening the abdomen the following conditions are found: The transverse and descending colons are much distended with gas and bulge through the opening as it is made, while the stomach lies lower in the abdominal cavity than normal, its greater curvature being about one finger's breadth above the umbilicus. But for this the abdominal contents occupy their normal positions.

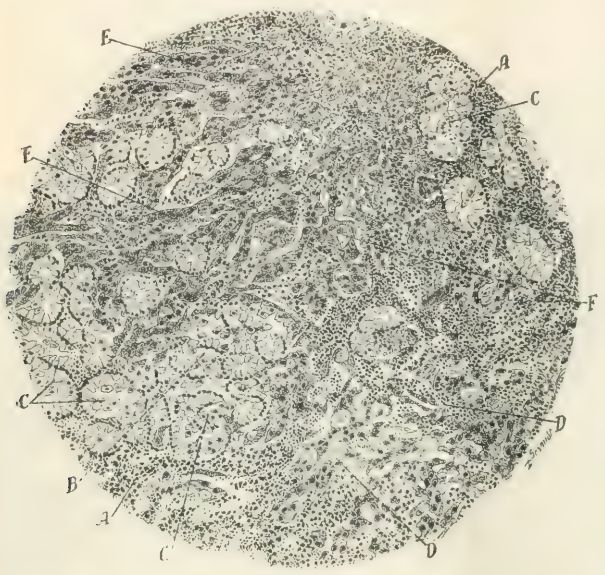

FIGURE 5.—A portion of the mucous coat near the ulcer. Objective, one-sixth; eyepiece, one inch. Magnification, about 350 diameters. Stained with hæmatoxylon and orange G.

EXPLANATION.—This plate shows very well the small-round-cell infiltration between the cross-sections of the gastric tubules, with here and there the cells very much crowded (*A*).

The exfoliation of the cells lining some of the glandular acini is also shown in places (*B*).

At one or two places the proliferation of the epithelial cells that line the glands, with breaking of these glandular structures and the escape of some of the cells into the surrounding tissue, is seen (*C*).

The entire obliteration of some of the glandular structures by masses of cancer cells (*D*), which in many places are strung out for some distance (*E*), and in a few others take on the pseudoglandular arrangement (*F*), is also well shown.

There is a small amount of sero-purulent fluid in the deepest portion of the abdominal cavity in which float numerous flakes of fibrin.

The peritoneum everywhere presents the following changes: Its vessels are engorged with blood, giving it a pinkish color and a slightly roughened surface. In places it is distinctly thickened, and in addition it has lost its normal lustre and is covered nearly everywhere with a thin film of soft whitish material, fibrin, that can be easily scraped off with the finger nail. Owing to the presence of this fibrinous exudate the various coils of the small intestine are glued together and the peritoneum covering them presents the same appearances as does that lining the abdominal cavity.

The mesentery likewise presents the same appearance, is thickened and bathed by a sero-purulent fluid, and more or less covered with fibrin. The position of the diaphragm on the two sides is normal.

Thorax: The ribs and costal cartilages present no changes. On removing the sternum the thoracic organs are seen to occupy their normal positions. The lungs lie free in the pleural cavities, except for one small adhesion that binds the lower lobe of the right lung to the diaphragm. In both pleural cavities there are about six ounces of clear serous fluid. The pleuræ present no changes.

The pericardium is apparently healthy and contains a small amount of a straw-yellow fluid.

The Heart: The heart is somewhat smaller than normal and weighs approximately eleven to twelve ounces. Its position is normal. Its surface presents no changes. The coronary veins are partly filled with dark fluid blood and the coronary arteries are soft and apparently healthy. All of the cavities of the heart are empty. There is no fluid or clotted blood in any of them. The aorta measures one and one-fourth inches in diameter; its walls are not thickened, and its intima is healthy. The same holds good for the pulmonary artery, which measures three-fourths of an inch in diameter. The closure of the aortic and pulmonary valves is perfect. The heart muscle is somewhat darker in color than normal. All of the valvular orifices are normal in size and the valve segments healthy. The thickness of the ventricle walls is likewise normal.

Lungs: In color, size, weight, and general appearance the lungs are normal. On section there is a small firm nodule, about the size of a hickory nut, in the apex of the right lung, which is probably a healing area of tuberculous disease. In the same location, in the left lung, there are a number of smaller nodules, each containing a cheesy material inclosed by a distinct capsule of dense, pearly-gray tissue, a fraction of a millimetre in thickness. Aside from these changes, the lung parenchyma is apparently healthy. A considerable amount of frothy pinkish fluid escapes from the left lung when it is cut and compressed. The bronchi are not altered.

The Liver: In size, weight, color, and general appearance the liver appears normal. In consistency it is softer than normal and is somewhat flabby. On section its color is darker than normal. The diaphragm is adherent in one spot to the upper surface of its left lobe. In all other respects this organ appears to be unaltered.

The gall bladder contains a moderate amount of greenish-brown bile, rather thick and sticky in consistency. There are no concretions.

The Spleen: This organ weighs four and a half ounces. Its capsule is smooth, and in color, consistency, and general appearance it seems to be normal.

The Intestines: The serous coat of the intestines, as already described, shows all the signs of an acute inflammation. The intestinal contents consist of a semifluid material and considerable gas. Upon opening the intestines the mucous membrane is seen to be very much discolored and in the upper portion, especially, to be bile stained. The glandular structures are unaltered, and the appendix, which is three and a half inches long, is healthy.

The Stomach: As already stated, the stomach is displaced downward, its greater curvature lying one finger's breadth above the umbilicus. Its serous coat is involved in the same general inflammatory process that involves the peritoneum and mesentery. Its vessels are all engorged, while its surface is roughened and

covered with a film of fibrin. Careful study of the stomach discloses the cause of the general peritonitis, for on its anterior aspect, not far from the pylorus and a short distance from the lesser curvature, there is a very small opening measuring from one and a half to two millimetres in diameter, through which there escapes a dark-colored fluid—the contents of the stomach.

Close inspection of the outer coat of the stomach in the neighborhood of this perforation shows, in addition to the general signs of inflammation already mentioned, many very slight, rounded elevations, the largest not so big as the head of a small pin, and many so small that they are only seen clearly with a magnifying glass. Palpation of the organ discloses considerable thickening and induration of its walls in the region of the pylorus, except just about the perforation, where the tissue seems to be very thin, this portion ending sharply in tissue that is unusually thick and firm.

Section: On opening the stomach it is found to contain about four ounces of a dark coffee-colored, mushy material which upon careful examination is seen to contain no blood. The mucous membrane appears to be quite normal and is thrown into prominent folds (see Fig. 2). If altered at all it is slightly thickened and swollen.

Near the pylorus there is a large, prominent ulcer, nearly circular in outline and measuring five centimetres in diameter. This has completely healed except in one place where perforation has taken place. The ulcer is evidently an old one. Its borders are elevated, thickened, slightly irregular, and but little undermined. Its base is comparatively smooth, there being but a few rounded elevations here and there. The portion of the stomach, which when examined from without gave the impression of being thin walled, is that which forms the base of the ulcer, just about the perforation, all the surrounding tissue being thickened and quite firm to the touch. Up to the edge of the ulcer the mucous membrane is intact. The pyloric opening has been involved in the ulcerative process and the contraction consequent to healing has resulted in an extreme grade of stenosis, so much so that the pyloric opening now admits only the end of a small lead pencil. Beyond this the duodenum appears to be healthy and does not share in the process of ulceration. The induration, which is most marked in the edges of the ulcer, is confined to its immediate neighborhood and rapidly fades away into the surrounding tissue.

The pancreas is adherent to the stomach in one or two places. It is of normal consistence and size, but is almost pure white in color.

The Kidneys: The right kidney is smaller than normal but healthy in appearance. Its capsule strips off easily. On section the cortex and medulla are of relatively normal dimensions and unaltered in appearance. The pelvis is normal.

The left kidney is considerably larger than the right but is of about normal size. In all respects it seems to be healthy. The pelvic viscera, brain, and spinal cord were not removed or examined.

Anatomical diagnosis: Acute general peritonitis due to perforation of the stomach and escape of stomach contents. Healed ulcer of the stomach with stenosis of the pylorus. Perforation of the stomach by a fresh ulcerative process engrafted on the old one. Probable cancerous infiltration of the walls and base of the old ulcer. Gastrectasia. Healed and healing pulmonary tuberculosis in both apices. Remains of a former, slight, localized pleurisy of the lower right lobe.

Microscopic Appearances of the Stomach Wall.[1]—Portions of the stomach wall were fixed in a four-per-cent. solution of formol, hardened in alcohol, embedded in both paraffin and celloidin, and stained both for a study of the histopathological changes and for any micro-organisms that might be present. The following appearances were noted:

The mucous coat: In the mucous coat the greatest changes were found in the immediate vicinity of the ulceration, and these gradually disappeared in the surrounding tissue. One of the most striking changes was the presence of enormous numbers of small round cells (Fig. 3). These were diffusely scattered throughout the entire thickness of the mucosa, being most numerous in its deeper layers, where in many instances they passed over and infiltrated the muscularis mucosæ and submucous layers. In many places these cells were grouped together into minute clumps, resembling in appearance early abscess formation. The farther one passed from the immediate vicinity of the ulcer, the fewer became these cells until finally they were not found at all. These small round cells were mostly of the character of the polymorphonuclear leucocyte of the blood, having lobulated and

[illegible] of the stomach [illegible] Objective, one-[illegible] eyepiece one inch. Stained with hæmatoxylon and orange G. Magnification, about 320 diameters.

EXPLANATION.—Cross-sections of bundles of muscle fibres from the muscular coat are shown (*A*), between which there are a large number of small-round cells (*B*) in places, and here and there large clumps of [illegible] cells (*C*), a few [illegible] this amongst *A* and *B*, and in formation [illegible] arrangement themselves in complete circles, while in others only a portion [illegible]

[1] The illustrations are taken from Hemmeter's "Diseases of the Stomach," P. Blakiston, Son & Co., Phila., 1897, and were made under the direction of Dr. Ames.

irregularly shaped nuclei which in some instances appeared to be composed of two or three separate parts, which upon close inspection were seen to be connected by slender threads of nuclear substance. A few of these cells resembled the small mononuclear leucocytes.

A further important change noticed in this layer of the stomach was the presence of larger and smaller clumps of quite large cells, each of which contained a clearly vesicular nucleus surrounded by considerable protoplasm. So closely were these cells packed in the clumps referred to, that only occasionally could the outline of the cell be made out. The clumps on casual observation seemed to be made up only of masses of nuclei and cell protoplasm; the outlines of individual cells not being visible (Fig. 3). In many instances the cells formed clumps of considerable size, that gradually tapered out into single rows of cells that lay between the cross-sections of the gastric tubules (Fig. 3). Groups and rows of these cells were most numerous in the very edge of the ulcer and were much scarcer a little distance from it. Occasionally these cells were arranged, as it were, in the form of a glandular acinus. This arrangement, however, was much more common in the submucosa, where the same cells were found in abundance (Fig. 5). These were apparently epithelial in character, and where they were most numerous the gastric tubules were completely destroyed, while about these areas the tubules were found to be very much altered (Fig. 3). Glandular acini were found from the walls of which the gland cells had been exfoliated; others to whose basement membrane a few cells were still attached, while within their lumina lay the degenerating bodies of those that had already been shed. While this process of exfoliation and cell death was most common in the areas in which the clumps of epithelial cells were found, one occasionally found an acinus the cells of which seemed to be in a state of reproduction. In these cases the lumen of the gland would be partly filled with new cells; about its margins there would occasionally be seen a double row of cells, and once in a while an acinus was found which had apparently broken and allowed the newly formed cells to escape into the interstices of the surrounding tissue, where they soon took on the character of the cells already described as forming the groups and clumps so numerous near the margins of the ulcer (Fig. 3 and Fig. 1 *A*). Whether or not this is a process of atypical cell reproduction which has given rise to all the extraneous cells of epithelial type seen in the tissue is a question. While glandular acini, such as we have just described, are not frequently found, it is possible that the epithelial cells so formed have continued to reproduce, as we know to be their custom in similar cases, and have so given rise to all of the new cells found. The supposition is at least plausible and would correspond closely to what Hauser and others have described as taking place in similar cases.

FIGURE 5.—A portion of an area in the submucosa largely composed of groups of cancer cells. Objective, one-sixth; eyepiece, one inch. Stained with hæmatoxylon and orange G. Magnification about 320 diameters.

EXPLANATION.—The fibrous tissue of the submucosa is infiltrated with many small round cells, which in some places are very numerous (*A*). The most prominent change appears in the numerous clumps of cancer cells, almost all of which lie in open spaces in the tissue (*B*). These clumps are like those seen in the other coats of the stomach, but the attempt at glandular formation is more marked here than in any other locality (*C*). In the upper part of the plate is seen the lower portion of the muscularis mucosæ (*D*), infiltrated with many small round cells, and containing a few of the masses of cancer cells.

There did not seem to be any formation of new fibrous tissue in this layer of the stomach, and a study of the proper secreting cells of the gastric glands did not disclose any important changes in them.

The muscularis mucosæ: While in general this layer of the stomach wall showed but little change, other than a moderate amount of small-cell infiltration, important changes were found in the immediate neighborhood of the ulcer in a number of places. In the areas referred to, the muscularis mucosæ was found to be very much thickened and its fibres widely separated by a most intense grade of infiltration with small round cells. Here in numerous places they were accumulated into small masses of about the head of a pin in size and lay one after another in a regular row. Between them the collection of cells was but little less pronounced. We evidently here had a collection of miliary abscesses, all the signs being those of an acute process (Fig. 6). It is to be remarked that although microscopic examination showed the muscularis mucosæ to be filled with numbers of these small abscesses, no pus could be expressed from the tissue at autopsy. In the neighborhood of these abscesses the accumulation of small cells had passed over and involved the deeper portions of the mucosa and to a less extent had spread also into the submucous coat for a short distance. So widely had the fibres of the muscularis been separated that it was difficult, with the small cells obscuring the image, to determine exactly what its boundaries were.

Only a very few of the cells of epithelial type, so numerous in the mucosa, were found in this layer. In a few places they were seen, and occasionally a small vessel was found plugged with them (Fig. 6, *C*).

The submucosa: About the base of the ulcer, and especially about the angle made where it turned upward toward the surface, the submucosa consisted of very dense, firm fibrous tissue, poor in blood-vessels. But

little of the infiltration with small cells, so marked in the upper two layers, was found. Just beneath the muscularis mucosæ in a number of places there were groups of cell clumps similar in all respects to those found in the mucous membrane. It was in this layer of the stomach wall that these cells were most frequently found to arrange themselves in the pseudo-glandular manner already described, which is well shown in Fig. 5, *C*, which represents an area of these cells found just under the muscularis mucosæ. Just under the base of the ulcer where it lies in the submucosa there were also a number of areas composed of groups and clumps of the same cells, and here too the pseudo-glandular arrangement was well shown.

The muscular layer: The chief point of interest in the muscular coat of the stomach was the presence of groups and masses of the epithelial-like cells between the bundles of muscle fibres in the neighborhood of the ulcer. In all respects these clumps and the cells that composed them were like those already described. They were not so numerous and the gland-like arrangement was not so frequently seen. The small-cell infiltration was also very much less marked (Fig. 4, *D*).

The serous layer: In describing the naked-eye appearance of the surface of the stomach it was stated that the serous surface in the neighborhood of the pylorus showed upon very close inspection, especially with a magnifying glass, minute elevated points varying in size from that of a pinhead to very much smaller. Upon microscopic examination these slightly elevated points were seen to be composed almost entirely of masses of cancer cells, like those already described. Instead of being diffusely scattered all through the serosa they were aggregated into small areas, each composed of numerous epithelial-cell clumps. The only points of difference noted were that the clumps themselves were considerably smaller than those in the other layers of the stomach wall, and that the individual cells were likewise smaller. No pseudo-glandular formations were found. One of these nodules in the serosa is admirably represented in Fig. 1 *B*. The serous coat in other places did not appear to be at all thickened.

Bacteriological Examination.—Sections were stained by Gram's method with both fuchsin and methyl violet for micro-organisms, with the following results: In the necrotic tissue lining the floor of the ulcer, the following organisms were found, all of which stained well, especially with methyl violet.

A bacillus. This appeared either as single, moderately long rods, sometimes staining solidly, sometimes showing clear open spaces in the protoplasm about the centre of the rod, while the ends stained deeply. In size these rods closely resembled anthrax bacilli and when they contained the open spaces just mentioned looked very much like anthrax rods with spores. In many instances this organism appeared swollen at one end, resembling in shape a baseball bat, and at other times one-half of the rod would be somewhat broader than the remaining half, the change in size being quite abrupt. Not infrequently what appeared to be the same organism was found in chains of from two to eight segments, some segments staining solidly while others showed the same open spaces found in the single rods. Even in the chain formation the peculiar morphology already mentioned was noted. By far the greater number of these organisms was found in the necrotic membrane on the floor of the ulcer, in both its superficial and deeper portions, but a few were also found in the living tissue beneath the ulcer, in the submucosa. In all respects this bacillus corresponded to one that was cultivated from the stomach washings and from the vomit, and it agrees with the description of a bacillus frequently associated with gastric carcinoma given by Oppler and Boas and by Kaufmann, and known as the "Oppler-Boas lactic-acid" bacillus. It is of peculiar interest in this case because of its association with the carcinoma engrafted on the old ulcer, as already mentioned.

Beside this organism the sections also showed, both in the necrotic base of the ulcer and in the living tissue below it, a few micrococci arranged in clumps and occurring singly, but never found in chains. While these were found in the location just mentioned, it is to be noted that a most careful search failed to reveal any micro-organisms whatever in connection with the numerous small abscesses found chiefly in the muscularis mucosæ and mucosa in the neighborhood of the ulcer.

A third organism was also found which, however, we have not as yet been able to classify exactly. In shape and general appearance it resembled very closely an ordinary yeast cell but was very much smaller, since when studied with a one-twelfth oil-immersion objective it appeared even smaller than a yeast cell would when viewed with a one-sixth dry lens. The usual shape of these organisms was either circular or oval, and they often appeared as though in the act of budding, a small knob-like projection being found on one side, usually about one-fourth the size of the parent cell. Sometimes the organism appeared as a double cell,

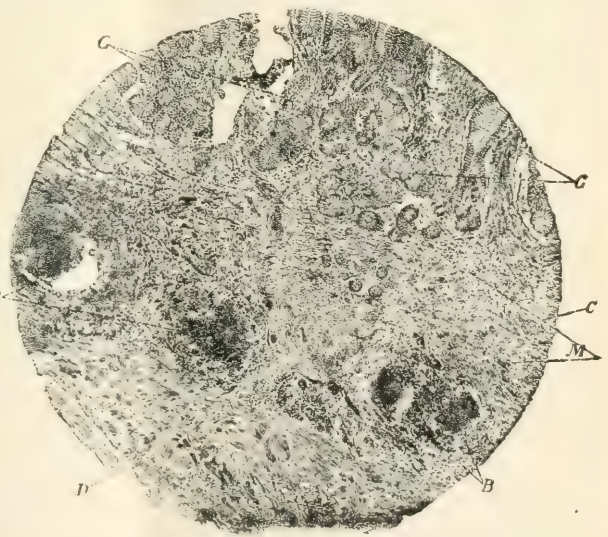

FIGURE 1.—Section showing the lower part of the mucous coat with the ends of some of the gastric glands, the muscularis mucosæ, and a small portion of the upper part of the submucosa. Objective, one-sixth; eyepiece, one-half. Stained with hæmatoxylon and orange G. Magnification, about 320 diameters.

EXPLANATION.—As in all the other sections, the small-round-cell infiltration is well marked, the cells chiefly filling up the muscularis mucosæ and invading the lower portion of the mucous coat. In the muscularis mucosæ these cells are aggregated into a number of small, circular, dense masses (*B*), miliary abscesses, between which they are but little less numerous. The fibres of the muscularis mucosæ have been widely separated by these cells. Few cancer cells are to be seen in this portion of the tissue, but in one place (*C*) they are found plugging completely a small vessel. In the upper part of the submucosa a few of the cancer cells can also be seen (*D*).

the two parts being of about the same size. In no instances were more than two such cells found together, and in this it differed from yeast, which often occurs in chains of several budding cells. The protoplasm of these cells stained a bluish-violet color and the capsule a somewhat darker tint. Within the protoplasm there was usually a number of darker-staining granules which were sometimes so numerous as to give the cell a coarsely granular look. In many respects these organisms resembled protozoa, to which class they probably belong. Their presence was probably purely accidental.

A good representation of the three organisms found in the tissue in this case is given in Fig. 1, *A*, *B*, and *C*.

The changes therefore found in the walls of the stomach point to three different morbid processes. In the first place, the ulceration. This was of long standing, as was evidenced by the fact that it had healed and in the healing had produced a gradually increasing pyloric stenosis. The fibrous tissue about the base and margins of the ulceration was firm, dense, and poor in blood-vessels. In one place the ulceration had progressed or a new ulcerative process had been re-established in the seat of the former and perforation had taken place, allowing an escape of stomach contents and the consequent production of an acute general peritonitis. This new area of ulceration was very limited in extent and the resulting perforation very small.

In the second place, within the tissue immediately surrounding the ulceration, that is, in the walls and base of the ulcer, there had developed a diffuse cancerous growth; atypical epithelial-cell reproduction had taken place, probably originating in tubules of the gastric glands, in some way affected by the process of ulceration and by the later process of cicatrization. The ulcerative process, it is conceivable, as pointed out by Hauser, reduces the natural tissue resistance, while the cicatrix formation produces a constant low-grade irritation; the result of these two being the stimulation of the glandular tissue to reproduce, the new cells being allowed to grow and develop in the spaces of a tissue less resistant than normal. That these cells may find their way into the lymphatics and blood-vessels is shown in Fig. 6, *C*, and in this way they may ultimately find their way into more distant parts. The peculiar tendency of these atypical glandular cells to reproduce the type of gland from which they originated by lining lymph spaces and spaces in the surrounding tissue is well shown in some of the sections. Had the patient lived long enough the new growth would probably have spread beyond the confines of the stomach wall and involved distant tissue, not only by successive invasions of contiguous tissue but also by being transported through the lymph and blood currents.

In the third place, a study of the tissue in the immediate vicinity of the ulcer showed an interesting condition that is not often seen. The lower layers of the mucous membrane and the muscularis mucosæ were the seats of a diffuse phlegmonous inflammation. Numerous very minute abscesses were found in the muscularis mucosæ and the signs of acute suppurative inflammation spead over and involved the under part of the mucosa as well. Owing to the presence of these small abscesses the muscularis mucosæ was greatly thickened and its fibres were widely separated by the large number of small cells present in the tissue. This particular morbid change is of interest, since it is so rarely found and especially because of its association with the ulcus carcinomatosum.

Let us resume once more the clinical aspect of this rare case. Pus is occasionally observed in gastric carcinoma,[1] and v. Leube mentions a case of simple gastritis with abundant purulent secretion, but does not classify this with phlegmonous gastritis. The discovery of the Oppler-Boas bacillus in the vomit was sufficient to induce us to refrain from an exact diagnosis of the cause of the stenosis. Oppler and Boas' first called attention to these characteristic large bacilli in gastric contents from cases of carcinoma. In unstained preparations they can be recognized by their considerable size, immotility, and form. Most of them have the shape of a baseball bat, gradually becoming thicker at one end. According to Kaufmann they possess the property of forming lactic acid abundantly from various kinds of sugar. In twenty cases of carcinoma Kaufmann succeeded in demonstrating their presence nineteen times. In only one case were they not found and in this lactic acid was also absent. There was a constant parallelism between the enormous occurrence of these bacilli and large amounts of lactic acid, and Kaufmann suggests that if this fact can be confirmed, the complicated analysis of lactic acid might be replaced by the simple investigation of a drop of the stomach contents or vomit under the microscope.

According to Schlesinger and Kaufmann,[2] who first succeeded in obtaining this form of lactic-acid bacillus in pure culture, the presence of numerous large bacilli of this kind speaks with great probability for gastric carcinoma. The negative result of searching for these bacilli is as valid a proof as the absence of lactic acid itself. If a pyloric stenosis is evident, they argue that the absence of the Oppler-Boas bacilli speaks against its origin from carcinoma. Although these organisms are not pathognomonic of cancer of the stomach, and although there are many other bacteria that can form lactic acid, they are nevertheless very significant and important for the diagnosis of carcinoma. F. Riegel[3] confirms the occurrence of this bacterium in enormous numbers in cases of gastric cancer and regards them as significant ("bedeutungsvoll").

The remarkable facts about this case were that it had undoubtedly originated in a gastric ulcer and conclusions were justifiable that gastrectasia was due to cicatricial stenosis. There were two signs that made us hesitate in making a definite diagnosis, and these were the constant presence of the Oppler-Boas bacillus and a pronounced progressive cachexia.

It will be evident from the appended analyses that lactic acid was found only once and that hydrochloric acid was present at every analysis, the smallest amount found being equal to 12° decinormal NaOH. From the work of Oppler, Kaufmann, and Schlesinger referred to, one may conclude that lactic acid is an unavoidable accompaniment of the Oppler-Boas bacilli, and that they rarely or never occur when hydrochloric acid is present in normal amount. Here was a case in which these characteristic bacilli were repeatedly found by Dr. Whitney and Professor Hemmeter in the stomach contents before death, and which were found, as already shown, by Dr. Ames in the walls of the stomach at autopsy, and in which there was normal and sometimes hyperacidity with an absence of lactic acid.

The absence of lactic acid we might explain by the fact that the man had for two weeks at a time been fed almost exclusively by the rectum, and when he really did receive nourishment by the stomach it contained mainly proteid diet, such as whipped egg, meat pulp, albumen water, and brandy. It is true that Ewald test meals were repeatedly analyzed, but then the work of Ferdin, Langguth,[4] and of Feiertag[5] makes

it clear that very little lactic acid is contained in the test breakfast, many times none at all. One essential condition for the production of lactic acid is the suppression of the secretion of hydrochloric acid; in this case there was some stagnation but normal amounts of hydrochloric acid, and at times some hyperacidity, so that the absence of lactic acid in the gastric contents is traceable to the absence, or nearly absence, of carbohydrate ingesta and to the presence of hydrochloric acid at all times.

According to the observations of Rokitansky and of Dittrich, and later of Hauser,[1] there can be no doubt that atypical cell proliferations, which may entirely possess the character of gastric carcinoma, may arise on the basis of a benign ulceration. Such a metamorphosis is, however, infrequent. In 1891 Kollmann[2] collected fourteen cases and in 1895 Boas could add but eight more,[3] so that although the phlegmonous suppurative gastritis which was found at autopsy is a rare disease, well authenticated cases of carcinoma arising from gastric ulcer are equally rare, thus making this report doubly interesting.

In from five to six per cent. of gastric ulcers a carcinoma develops in the margins.[4] The diagnosis is based upon the presence of progressive cachexia with tumor, and normal or supernormal secretion of hydrochloric acid.[5] In spite of absence of hydrochloric acid, however, a carcinoma may nevertheless have originated from an ulcer. The diagnosis is supported by the previous characteristic history of ulcer and the course of the disease. An ulcer does not suddenly strike into the existence of an individual as carcinoma does, and ulcus carcinomatosum occurs in individuals who, as a rule, have suffered for years with gastric pain. If hæmatemesis and bloody stools are recorded in the anamnesis, the diagnosis acquires some certainty.

The diagnosis between gastric carcinoma *ex ulcere* and tumor-like induration of a simple ulcer is difficult. Boas holds that in some cases the secondary metastasis in the liver or other organs, and such other signs as ascites, peritoneal carcinosis, etc., may give the deciding clew. Such aids, however, are very rarely obtained. Among other conditions hypertrophic stenosis of the pylorus may have to be eliminated. Cases have been described in which the only symptoms were those of ulcer with cachexia, no tumor mass at the pylorus being palpable, and which yet at autopsy showed an ulcus carcinomatosum.

We had no hesitation in establishing a diagnosis of carcinoma in our own case, based upon the progressive cachexia, the tumor mass at the pylorus, and the presence of the Oppler-Boas bacillus, and as there was no doubt about the previous existence and probable persistence of an ulcer the diagnosis of ulcus carcinomatosum was made very probable.

The diffuse suppurative (phlegmonous) gastritis which was found at the autopsy in the form of numerous miliary abscesses in the mucosa and in the muscularis mucosæ, in the floor, and in the margins of the neoplastic ulcer, was not diagnosed ante mortem, for although micrococci and pus were observed in the gastric contents, these are not infrequently noted in connection with carcinoma, and as the temperature was almost continually normal or subnormal, the possibility of phlegmonous inflammation of the stomach did not enter our minds, and finding it in the sections was a great surprise. The method of hardening, sectioning, staining, etc., has already been described by Dr. Ames, who made the autopsy and studied the tissue with the assistance of Dr. A. A. Huntley, his assistant in the pathological laboratory in the Baltimore Medical College.

FIGURE 7.—Section of tissue from twelfth; eyepiece, one inch. Stained Magnification, 1,060 diameters.

b, A micrococcus which occurs singly and in clumps, but never in chains. the Oppler-Boas bacillus and the next organism to be described were found both

yeast cell. Budding forms are seen, and the granular protoplasm in some, and the few large, deeply staining dots in others, are well represented.

This section should have been in colors; owing to its complex reproduction it was impossible to insert it except in black, and in consequence the organisms only are shown in their exact positions, the tissue in which they lay not being represented.

In many particulars our case resembles one of phlegmonous gastritis following gastric cancer reported by S. Mintz,[1] who at that time collected forty-one cases. In a new compilation we give all the cases of phlegmonous gastritis referred to in the literature, amounting in all to ninety-five references, as well as a list of all works referring to the subject. These are mainly from the reports of Mintz,[2] the text-books of Ewald, Boas, Rosenheim, and Riegel; the fourth volume of the Edinburgh Hospital Reports; an article by R. F. C. Leith, pp. 51–114; from Debove and Rémond,[3] and from the various journals quoted. It is appended under the bibliography at the end of this article, together with the bibliography of ulcus carcinomatosum.

Analysis of Stomach Contents of George Williams.—March 4, 1896, Maryland General Hospital. Meal at 11:30 A.M. Ewald meal at 3:30. Contents of stomach examined at 4:40.

Macroscopic examination: Amount, 180 c.c. Clear. Acid odor. No apparent fermentation. Normal amount of mucus. Rice. Small pieces of meat probably indigestible. No blood. Small amount of bile.

[2] L. c.

[3] "Maladies de l'Estomac," p. 1[illegible].

Chemical examination: Reaction acid to litmus, congo paper, and Boas reagent. Negative to Uffelmann's test. Total acidity: 5 c.c. filtered contents treated required 5.4 c.c. alkali to neutralize. Total acidity, 108.

Dr. Whitney's conclusions at this time were as follows: Marked hyperacidity. Some atony. Probably gastric ulcer with pyloric obstruction.

The patient was put upon rest, milk diet, bismuth, Carlsbad water, Blaud's pill with arsenic for a time, lime water, and bicarbonate of sodium. Local treatment for pains.

Result: Cure. Patient discharged May 1, 1896.

Second Examination: Stomach contents drawn at 8 A.M. No food since the previous day.

Macroscopic examination: Amount, 900 c.c. Color brownish. Large amount of grumous disintegrating blood. Traces of pus. No other solid particles. Odor normal. No bile. No excess of mucus.

Chemical examination: Acid to litmus. Acid to congo paper. Acid to dimethyl. Free HCl present. Lactic acid absent. Sugar, very faint trace. Erythrodextrin absent. Peptone present. Acidity: free HCl, 32 per cent. Organic acids and acid salts, 29 per cent. Combined HCl, 1 per cent. Total acidity, 62 per cent.

December 6, 1896. Maryland General Hospital meal at 8 A.M. Ewald meal at 12 M. Contents drawn at 1 P.M.

Macroscopical examination: Contents large, 1,200 c.c. Odor slightly offensive. Small bits of bread from Ewald meal. Egg yellow present from Maryland General Hospital meal. Small bits of tissue, apparently meat. Small amount of mucus. No blood. No bile.

Microscopical examination: In addition to food the small bits of tissue showed numerous flat epithelial cells. No sarcinæ. Sections will be made of the tissue.

Chemical examination: Acid to litmus. Acid to congo. Acid to dimethyl-amido-azo-benzol. Free HCl present. Lactic acid absent by Boas test. Acetic acid (?). Erythrodextrin absent. Sugar present. Peptone present. Free HCl, 14 degrees. Combined HCl, 24 degrees. Acid salts and organic acids, 46 degrees. Total acidity, 84 degrees.

December 7, 1896.—Maryland General Hospital meal at 8 A.M. Ewald meal at 12 M. Contents drawn at 1 P.M. The stomach was washed thoroughly at 7:30 A.M. and all drugs were stopped.

Macroscopic examination: Contents large, about 350 c.c. Filtrate faintly cloudy, 300 c.c. No blood, bile, or excess of mucus. Odor faintly sour and slightly unpleasant. No meat or milk left from Maryland General Hospital meal. Small bits of egg yellow and bread. No bits of mucosa to be found.

Chemical examination: Acid to litmus, congo, and dimethyl. Free HCl present. Lactic acid absent. Acetic acid (?). Sugar present. Erythrodextrin absent. Peptone present. Total acidity, 70 degrees. Free HCl, 12 degrees. Combined HCl, 24 degrees. Acid salts, etc., 34 degrees.

December 17, 1896.—Last food given the evening of December 16th. Contents were drawn about 8:30 A.M., December 17th.

Macroscopic examination: Amount about 500 c.c. Odor faintly unpleasant. No food contents recognizable. Small particles of bismuth from former days. No blood, bile, or excess of mucus. Pus present. Filtered readily. Filtrate clear. Slightly brownish tinge.

Chemical examination: Acid to litmus, congo, and dimethyl. Free HCl present. Lactic acid absent. Butyric acid absent. Acetic acid absent. Erythrodextrin absent. Sugar present. Peptone present. Total acidity, 84 degrees. Free HCl, 20 degrees. Acid salts and organic acids, 57 degrees. Combined HCl, 7 degrees.

January 8, 1897.—Stomach washed out in the morning and then Maryland General Hospital meal at 8:10. Ewald meal at 12:10. Contents drawn at 1:10.

Macroscopic examination: Amount, 1,100 c.c. Odor offensive. Small amount of blood shown in the filtrate. Slight excess of mucus, no bile. Bread, meat, egg, rice, present in contents. Filters slowly. Filtrate brownish, clear.

Chemical examination: Acid to litmus, congo, dimethyl. Free HCl present. Lactic acid absent. Peptone present. Erythrodextrin present in small amount. Sugar present, nearly normal. Free HCl, 27 degrees. Combined HCl, 7 degrees. Organic acids and acid salts, 53 degrees. Total acidity, 87 degrees.

Ferments: Pepsin and rennet present in about normal power.

Synopsis of the Urine Examinations of George Williams:—The amount varied from 470 to 680 c.c. in the twenty-four hours. The reaction was in every instance but one alkaline. The odor was as a usual thing normal. The specific gravity varied from 1.021 to 1.032. Albumin was never detected. Sugar was never detected. Globulin was never detected. Indican was always in excess. Urophen was normal in three examinations and in excess in two. Urea varied from 12.22 to 20.06. Uric acid varied between 0.3326 and 0.4737. Chlorides varied from 0.658 to 1.53 gm. as NaCl. Phosphates varied from 0.7884 to 1.3 86 gm. as P_2O_5. Bile pigments were always absent. Acetone was absent in all but one examination, when it was marked. Bile salts were always normal. Blood was always absent. Hæmoglobin was always absent. Diacetic acid was always absent. Creatinin was always in excess. Uroerythane was present but once. The microscopic examination showed epithelial cells, some pus, triple phosphates, mucus, and amorphous urates.

THE SCIENTIFIC TREATMENT OF TUBERCULOSIS.[1]

BY JOSHUA LINDLEY BARTON, M.D.

[illegible]

THE discovery of the tubercle bacillus by Dr. Koch in 1881 marked an epoch in the history of tuberculous disease; first, because up to that time the etiology of the disease was obscure; and secondly, the treatment, being largely symptomatic, was defective.

"The great desideratum in nomenclature, as applied to disease, is that the name of each disease shall express the morbid condition involved." Not only is the proper nomenclature of this disease, however, in doubt, but also the exact pathological conditions intended to be described by the synonyms used. We find it mentioned by medical writers as consumption, tuberculosis, and phthisis. These terms are applied to a number of inflammatory conditions which may be either acute or chronic, incipient or far advanced, pneumonic, tuberculous, or fibroid. Granting that in nearly if not quite all of these cases the tubercle bacillus is the cause of the disease, it still remains true that clinically much perplexity exists because of a failure sufficiently to appreciate the fact that "tuberculosis and phthisis are distinct and different conditions," while the term consumption may be applied to an entirely different form of disease.

The practice of medicine is both a science and an art; but "Science is knowledge reduced to principles;" "Art is knowledge reduce to practice." We can, therefore, hardly wonder that our art so often fails to master this disease, when we ignore the first principles of sound practice and treat the disease by name, regardless of the pathological conditions.

Since 1881 tuberculosis has severely taxed the ingenuity of the profession. The etiology of the disease being so simple and due to one cause, the conclusion has been natural that if we can remove the cause we shall cure the disease. We have, therefore, been too apt to ignore the patient, considering him simply as a culture medium for the disease germs, and have paid our respects almost wholly to the tubercle bacilli.

Tubercle bacilli are minute vegetable bodies, about one-three-thousandth of an inch in length. They are ubiquitous, omnipresent—in the water we drink, in the air we breathe, and in the food we eat. They seem to have neither beginning of days nor end of years. High and low, rich and poor alike, are liable to their visitations. It is, therefore, of much interest to inquire why it is that some individuals are attacked while others escape.

The consensus of clinical experience and scientific opinion seems to be that malnutrition, heredity, and irritation of the respiratory mucous membrane, from whatever cause, are all-powerful factors predisposing to the disease; and that when the tubercle bacilli gain entrance to soil prepared by one or all of these agencies they take root, and shortly the sufferer presents himself with the clinical phenomena of pulmonary tuberculosis.

Curability of the Disease.—Medical authorities[2] are quite unanimously of the opinion that a large percentage of the incipient cases can be cured by appropriate treatment, while in the more advanced and chronic forms the disease may be greatly delayed and life rendered fairly comfortable. But it should not be forgotten that *alterum alterius auxilio eget* is a *conditio sine qua non* to success.

Prophylaxis.—The old adage that an "ounce of prevention is worth a pound of cure" is eminently true in connection with pulmonary tuberculosis. But prophylaxis should embrace not only a prohibition of expectoration in public places and an additional hospital for the proper care of a few of those who are ill; it should also provide for the destruction of all infected animals and for our tenement-house population large, airy living-rooms into which the glorious sunshine may come.

Plan of Treatment.—The plan of treatment should take into consideration, first of all, the pathological condition, *i.e.*, whether the case is one of simple tuberculosis or of phthisis; whether the disease is quiescent or progressive; and whether the conditions of cure are present or absent; *i.e.*, whether the patient has the vitality or recuperative power to respond to the treatment.

Hygienic Management.—The general health of all persons suffering from this disease should be carefully promoted. Their sleeping-apartments should be large and well ventilated; they should spend several hours each day in the open air; their nervous systems should be stimulated to healthy action; physiological errors in digestion and assimilation should be corrected; the blood should be improved in quality, so that it may furnish to the individual cells those elements which will build up and improve the tissues.

Mechanical Treatment.—No mechanical device yet suggested exceeds in value the "pneumatic cabinet," as a therapeutic agent in the treatment of pulmonary diseases. "The mastery of its physics, a thorough knowledge of physiology, and a correct appreciation of the pathological condition in each particular case are of course indispensable."[3] Some of the most important results obtained by a judicious use of this instrument are as follows, viz.: the muscles of respiration are developed; the lungs are made to expand; portions of lung tissue which have been comparatively idle are made to perform their physiological function; "inflammmatory stasis is prevented; septic products and mechanical obstruction to circulation and respiration are removed; lymphatic absorption is increased, and the nutritive supply is augmented."[4]

Topical Treatment.—A recent writer upon "The Surgical Treatment of Tuberculosis" makes the assertion that "tuberculosis is amenable to treatment in direct ratio to our ability to attack it locally." If this is true of tuberculosis of the skin, bones, joints, kidneys, and pleura, it is also true of tuberculosis of the lungs.

The late Dr. Horace Green, of this city, as long ago as 1838, taught that pulmonary tuberculosis could be treated locally by means of injections into the trachea and bronchi through the mouth and larynx. In 1840 he brought the subject before the New York Medical and Surgical Society, and reported fifteen cases of severe laryngeal and bronchial disease which had been cured by this means. Between October, 1854, and February, 1856, he had treated one hundred and six cases. Of these, seventy-one were classed as cases of tuberculosis. Of these tuberculosis cases, thirty-two were considered as cases of advanced tuberculosis, *i.e.*, cases

[3] Dr. Von Ruck.

[4] Dr. C. E. Quimby, in a paper read before the American Climatological Association, June, 1892.

in which tuberculous cavities were recognized; and thirty-nine as cases of early tuberculosis. Of the subjects of advanced tuberculosis, twenty-five were more or less improved—their lives being apparently prolonged by this means of medication. Of the thirty-nine cases of incipient tuberculosis, twelve had apparently recovered at the time the report was written, and five more were nearly well. Of the remaining twenty-two cases, seventeen were greatly improved, three were moderately benefited, and three failed to receive any benefit whatever. Of the twenty-eight cases of bronchitis, sixteen were cured, and all of the others greatly benefited. In six cases of asthma treated by this means—in all except one—the disease was entirely removed. Four years later in a paper read before the Medico-Chirurgical College, he adds: "Such has been the amount of success which has continued to attend this plan of treatment that I am now ready to affirm, after an experience of many years in a field of observation unusually large, that, if I were required to relinquish all other known therapeutic measures or topical medication in the treatment of thoracic diseases, I should choose the latter with hygienic means alone, in preference to the entire class of remedies ordinarily employed in the treatment of these diseases."[1]

The technique is simple. An ordinary aspirating syringe with an endo-laryngeal tube, a head mirror, a laryngeal mirror, a Mackenzie condenser, and a cocaine spray constitute the necessary apparatus; while a steady hand, a cool head, and some knowledge of laryngology will enable any physician to treat the disease topically by means of intrabronchial injection.

"This method of medication has several advantages, viz.:

"1. The remedy is applied directly to the irritated mucous surface.

"2. It immediately alleviates the most distressing symptoms, adding at once to the comfort of the patient.

"3. In a certain number of cases the antiseptic effect of the medicine is very pronounced, as shown by the longer interval between febrile attacks, and by their lessened intensity when they do occur.

"4. The tracheal and bronchial mucous membrane rapidly absorbs the medication, so that we may expect a general as well as a local effect.

"5. We avoid disturbing the patient's stomach with nauseating doses, and the shattering of his nervous system with opiates.

"6. This method of alleviating the most distressing and annoying symptoms does not interfere in the slightest degree with any other line of general treatment which may be deemed advisable.

"7. In cases characterized by an atrophic condition of the tracheal mucous membrane, or of pulmonary disease with cavitation leading to retention and decomposition of the secretions, intrabronchial injection will remove the disgusting fetor of the breath consequent upon this condition."[2]

Local applications to diseased areas, in phthisis, may also be made by means of intrapulmonary injection. An exhaustive review of the history of this procedure will be found in an excellent paper written by Dr. Beverley Robinson and published in the MEDICAL RECORD, of January 10, 1885.

The technique is fully described in an admirable paper by Dr. J. Blake White and published in the MEDICAL RECORD of November 13, 1886. The results obtained by means of topical medication in pulmonary diseases should inspire us with confidence that a very large number of cases may be amenable to scientific treatment which were formerly considered hopeless.

[2] Dr. Joshua L. Barton, in a paper read before the laryngological section of the New York Academy of Medicine, March 25, 1890.

Medicinal Treatment.—A long list of remedies has been suggested for administration in tuberculosis; but with the exception of those which promote nutrition there is little to encourage their use. When the fact is clearly recognized that a restoration of normal nutrition is of greater value in the treatment of tuberculous disease than the whole class of so-called antiseptics, and that, owing to the physiological and pathological complications, a specific remedy is out of the question, a brighter day will have dawned for both patient and physician.

There are two remedies, however, in addition to those commonly prescribed, to which I wish especially to call attention. First, the chloride of gold and sodium with the iodide of manganese, brought prominently before the profession as a therapeutic agent in tuberculosis by our honored president, Dr. J. Blake White, is a most valuable remedy as well as a powerful nutritive stimulant, and is deserving of a much more extended trial than it has yet received. Secondly, the tuberculin of Koch, "regarded for a short time as a specific in tuberculosis," is a remedy of the greatest value when used in small doses, as suggested by Dr. Von Ruck. After an experience of some years his testimony is that "its effects are as reliable and uniform as we can expect them to be when we take into consideration individual idiosyncrasy, the stage of the disease, and the pathological complications which are usually present." Doctors Trudeau, Muir, Bermingham, and many others bear testimony to its therapeutic worth, and I may venture to add that my own experience with this remedy has been of the most satisfactory character.

The initial dose should never exceed one-twentieth of a milligram and should be increased only after tolerance has been established, the rule being never to give a dose large enough to cause a febrile reaction. The second week the dose may be increased to one-tenth of a milligram, and the third week to one-fifth of a milligram, and so on, until the maximum dose which a patient can take has been reached. Should a reaction occur the remedy should be discontinued for a time and then resumed, the minimum dose being given as in the first instance.

It is best administered in a one-half-per-cent. carbolic solution, so prepared that five minims of the solution will contain one-twentieth of a milligram of the tuberculin. This may be injected with a hypodermic needle into any convenient part of the body.

"Whenever a point is reached where the improvement is radical and the active symptoms have entirely subsided, the remedy should be discontinued and the patient kept under observation for some weeks. If the cure seems to be permanent the patient may then be discharged; otherwise a repetition of the treatment is necessary."[1]

Change of Climate.—The theory that tuberculosis can be speedily eradicated or more successfully treated by establishing hospitals and sanatoriums in certain localities is fallacious in the extreme. Back of tubercle bacilli are causes which are operating to produce malnutrition and a lowered vitality. The people need to be taught how to live rightly. Instead of more sanatoria, let us have schools of physiology and hygiene, and instead of introducing military drill let the public schools teach cooking and dietetics.

Climate undoubtedly exerts some influence over the processes of nutrition, but it has been greatly overrated as a curative agent in pulmonary tuberculosis.

Modern methods of scientific treatment, combined with a liberal diet of good nourishing food and several hours spent each day in the open air, are worth far more than any change of climate can possibly be to the vast majority of sufferers from this disease.

[1] Dr. Von Ruck.

Length of Time during which Treatment Should be Continued.—If eternal vigilance is the price of liberty, eternal patience and perseverance upon the part of both physician and patient are the price of success and of cure in connection with pulmonary tuberculosis. The treatment must be continued, not only until the tubercle bacilli have disappeared, but until the general condition and nutrition of the patient have been restored.

A plan of treatment which combines the hygienic, the mechanical, the topical, and the medicinal is full of hope for those who suffer from this disease. The day is not far distant—indeed it has already come—when a large class of patients may be led to hope not only for a temporary improvement in their condition, but for a radical cure for their disease.

I have treated during the past year twelve cases of tuberculosis; six of these were cases of early tuberculosis and six cases of advanced tuberculosis, *i.e.*, cases in which either consolidation or cavities were recognized. Of the early cases, two have apparently recovered and three more are nearly well, while all of the others have been greatly benefited.

Report of Twelve Cases.—Case I.—Mr. B——, aged twenty-eight, works in tobacco factory. This patient presented himself at my clinic at the department of out-door poor, Bellevue Hospital, in March, 1894. He complained of cough, night sweats, loss of flesh, and profuse expectoration. He had been taking cod-liver oil and creosote for six months with no apparent benefit. Examination revealed prolonged expiration with fine râles over the whole upper lobe of the right lung. The sputum showed tubercle bacilli. In this case the cod-liver oil and creosote were continued and the patient was given one-twentieth of a milligram of tuberculin three times a week by hypodermic injection. This treatment was continued for five months. The patient improved steadily, the cough gradually became less, the expectoration ceased, the appetite improved, the night sweats stopped, and there was a marked increase in weight. The treatment was discontinued for two months and then resumed, intrabronchial injections three times a week being added.

This treatment was continued for six months longer, when, all the active symptoms having disappeared together with the tubercle bacilli, the patient declaring that he felt perfectly well, he was discharged cured. This patient has since been kept under observation and is to all appearances in perfect health.

Case II.—Mr. P——, merchant, aged thirty, had measles in April, 1896, from which time his general health has been much impaired. He began to cough about July, 1896. At the time when he came under observation he was expectorating about two ounces daily, temperature ranging from 99° to 101.6° F. Examination revealed prolonged expiration over the apex of the left lung, with slight roughness of the breathing sounds. The sputum contained tubercle bacilli. This patient was treated by intrabronchial injection, hypodermics of tuberculin, and the pneumatic cabinet. The treatment was continued daily and the patient steadily improved until November 27th, when he suddenly developed pneumonia after an exposure to cold. For three weeks the treatment was discontinued with the exception of the intrabronchial injections, which were repeated two or three times a week. At the end of the third week the full treatment was resumed and continued daily, and the patient improved all of the time until February 18th. An examination of the sputum upon that date showed that the tubercle bacilli had disappeared. Treatment by intrabronchial injection and the pneumatic cabinet was continued, however, until March 17th, when, the active symptoms having all disappeared, the patient was discharged apparently cured.

Case III.—Mr. S——, pilot, aged thirty-four. This patient came under observation in the lung department of the New York Throat and Nose Hospital, August 28, 1896. No definite history of his previous condition was obtained. He complained of cough, expectorated freely, was losing flesh, and the sputum contained tubercle bacilli. The trouble was located in the apex of the right lung. This patient was treated three times a week by intrabronchial injection, hypodermics of tuberculin, and the pneumatic cabinet. This was continued until December 26th, when, the active symptoms having disappeared together with the tubercle bacilli, the treatment was discontinued. With the exception of a slight cold, this patient has continued to improve and is now to all appearances in perfect health.

Case IV.—Mr. B—— had pleurisy in the right side in September, 1895, and had not been well since. He complained of cough, rise of temperature, and expectoration. Examination revealed consolidation of the middle lobe of the right lung and the sputum contained tubercle bacilli. Treatment has been by intrabronchial injection, the pneumatic cabinet, and hypodermics of tuberculin, repeated daily since November 30th. There is a marked subsidence of all of the active symptoms. Respiration is much better and the general condition and nutrition of this patient are greatly improved. He is still under treatment.

Case V.—Mr. H——, aged twenty-nine, plumber, some years ago strained his left side, after which he spat up blood. He has had six hemorrhages, has cough, and expectorates quite freely. Examination revealed prolonged expiration over the left apex, with subcrepitant râles at the level of the second rib, near its junction with the sternum. The sputum contained tubercle bacilli. The treatment in this case has been by intrabronchial injections, the pneumatic cabinet, and hypodermics of tuberculin repeated daily. The cough and expectoration have been much diminished and he has increased in weight. His general health has been much improved. He is still under treatment.

Case VI.—Miss W——, aged fourteen, came under observation December 29, 1896, complaining of cough, loss of appetite, night sweats, and vomiting after meals. Examination revealed prolonged expiration over the upper lobes of both lungs. The sputum showed tubercle bacilli. The temperature ranged from normal to 101° F. The treatment in this case has been by intrabronchial injection, pneumatic cabinet, and hypodermics of tuberculin repeated three times a week, with an occasional dose of sulphate of atropine for the night sweats. Her general health has greatly improved. The night sweats have ceased. She eats well and has gained fourteen pounds in weight. She is still under treatment.

Case VII.—Mr. C——, bookkeeper, aged twenty-four. Family history not very good. Cough for three months. Expectorates freely. Has night sweats. Whole upper lobe of right lung involved. The sputum does not contain tubercle bacilli. This patient has been treated by the pneumatic cabinet, intrabronchial injections, and hypodermics of tuberculin repeated three times weekly since January 9th. There has been a marked improvement in his general condition; cough is less and the expectoration diminished. The night sweats, however, continue. He is still under treatment.

Cases Reported by Dr. Carpenter.—Case VIII.—Mr. ——, aged thirty-five years, German bartender. Cavity at left apex, both lungs diseased throughout, night sweats very profuse, bloody expectoration, breathing very shallow, had lost over thirty pounds in last year, bacilli numerous. This man had been taking creosote three months, with slight improvement, before I used the intrabronchial injections. He has been

steadily improving in every way since and at the present time is working regularly; he coughs very seldom, has no expectoration; night sweats have stopped entirely; he has a ravenous appetite and has gained thirteen pounds in weight. Intrabronchial injections began June 6, 1896. For the past month examination has failed to disclose any bacilli.

Case IX.—Mr. M——, aged twenty-eight years, German salesman. For one year previous to treatment by intrabronchial injection he had a slight cough, and, although he had been under constant treatment, had lost twelve pounds and his condition had not improved. Both lungs were affected, and he had night sweats two or three times a week. On September 3d this patient received the first intrabronchial injection which I repeated three times a week. Night sweats have entirely disappeared; he coughs very little, principally in the morning after getting up; the expectoration is very slight and his appetite is much improved. The patient looks much better and shows improvement in every way. October 7, 1896, says he has gained four and one-half pounds in the past month. Still under treatment.

Case X.—Mrs. M——, aged twenty-seven years, married three years, had a cough for over one year. Slight expectoration; occasional night sweats, not very severe; bacilli found in expectoration not very numerous; slight dulness found over apices of both lungs; has tuberculous laryngitis. Intrabronchial injections began August 15, 1896, and were repeated three times a week. Throat symptoms began to improve from the beginning; cough is much relieved; appetite has returned. October 7, 1896, has not had a night sweat in over two weeks; her breathing is much freer. Still under treatment.

Case XI.—Mr. S——, aged thirty years. Marked consolidation at the apex of the left lung; nodules throughout both lungs. He also has tuberculous laryngitis. Numerous bacilli were found. First intrabronchial injection June 16th; these were continued daily, beginning with one-half drachm and increasing to two drachms; creosote internally, beginning with three drops and increasing to ten drops three times a day. June 23d, cough softer and easier; expectoration more free; throat feels much better; night sweats diminished. September 28th, cough much improved; expectorates very little; has not had a night sweat in six weeks; throat does not bother him at all; has gained five and one-half pounds in weight; about half the previous number of bacilli found in sputum.

Case XII.—Mr. S——, aged thirty years, salesman, had been sick six months. Severe cough and night sweats, profuse expectoration, gradual emaciation. Took aseptolin without any improvement whatever. First intrabronchial injection June 1st, repeated daily until July 1st, then discontinued because he was feeling so well. At the first examination bacilli were quite plentiful. June 25th, bacilli were very few. After the injections had been discontinued for two weeks bacilli became more numerous again and he dropped back into his old condition. He went to the country July 15th, and I have not seen him since. I believe in this case that if patient had continued treatment a good result would have been secured.

Iodoformism, after wounds and operations, and especially burns due to a localized or generalized reflex polyneuro-dermatitis, has been studied by Tussau. After a period of toleration in which the wound does well an inflammatory area develops at the periphery of the wound and a lymphangitis may develop in a limb, followed by necrosis which may threaten loss of limb if not of life. Iodoformic herpes is only the first stage of this reflex polyneuritis.—*Dublin Medical Journal.*

A DISCUSSION OF THE COMPOSITION OF CREAM AND A CONSIDERATION OF THE DESIRABILITY OF ESTABLISHING A STANDARD.[1]

By J. H. HUTCHINSON, M.D.

"Modified milk" has become such a routine prescription for bottle-fed children that all of its components deserve the most careful study, and one of them, cream, has apparently as yet had less than its share. For those cases in which the condition of the stomach demands more than ordinary care the milk laboratory has demonstrated its usefulness, even perhaps its necessity; but laboratory milk is expensive and its use is therefore practically limited. Different pædiatrists have taught us how the materials for home modification may be supplied by letting the milk stand a sufficient number of hours and then skimming it for the cream; by this means a cream of sufficiently nearly constant composition can be obtained, but this method delays the preparation of the bottles of milk to a somewhat late hour in the day, and there seems to be no reason why the cream required should not be obtained directly from the dairy, just as the milk is obtained. There is also sufficient economic reason for an inquiry into the amount and character of a food material received daily by an immense number. Led by those considerations, I have tried to find out something of the present condition of the cream supply in this city, and, as published matter on cream is rare in medical literature, I have turned to the reports of the dairy division of the United States department of agriculture and to the reports of various agricultural experiment stations. This information has been supplemented by much most valuable advice from Dr. E. J. Lederle and also from Chemist Martin, of the city health department; from Mr. E. N. Ehrhart, sanitary engineer; Mr. J. A. Howell, of the Howell Condensed Milk and Cream Company; Mr. L. B. Halsey, of the Sheffield Farms Company, and others.

The Milk Reporter, the official journal of the milk trade, states that during 1896 there were received in New York City practically nine million quarts of cream, a daily average of nearly twenty-five thousand quarts, and three hundred and twenty million quarts of milk. The district which supplies this immense amount is shown by the statement that about two million cans came over the D., L., & W. R. R., one and a half millions over the Erie, the same over the Ontario, and the rest in smaller amounts over nine or ten other roads. Orange, Dutchess, Chenango, and Delaware counties supply over one-half of the total amount sent. The farthest point from which milk is shipped to New York is over three hundred and twenty-five miles away, and the journey to the city occupies about twenty-four hours. Much the greater part, however, is brought in less than ten hours.

Cream comes to the city either in forty-quart tin cans or in glass bottles; cans are most used on account of their smaller freight charges (twenty-eight cents for forty quarts in a can, forty cents for the same amount in bottles). According to its method of manufacture it is divided into two classes: gravity, *i.e.*, hand-skimmed, or Cooley cream, and machine or separator cream. The proportion of machine cream to the gravity is said to be about ten to one. About half of the cream supply of New York is sold to families, the other half is sold to ice-cream factories, bakers, and confectioners. The immense amount used in these trades is shown by the fact that during the four summer months of May, June, July, and August, 1896, there was received a total of about four million

[1] Read before the section on [illegible] meeting of the Academy of Medicine, May 25, 1897.

six hundred thousand quarts of cream, *i.e.*, more than in the other eight months put together.

The gravity cream, which is almost entirely taken by the ice-cream makers, restaurants, and hotels, varies in fat content, although the great bulk of it ranges from twelve to sixteen per cent. It is usually raised by gravity in "Cooley" cans, which have a faucet at the bottom by which the lower part of the contents can be drawn off without disturbing the upper; these are submerged in cold water for about twenty-four hours and then skimmed by drawing off the milk below the cream. The cream thus collected does not keep well and there is said to be frequently added, therefore, a composition of borax and salicylic acid, called "Preservitas."

The machine cream is separated from the milk by the use of some one of the several centrifugal separators. It can be made very quickly, and therefore does not need the twenty-four hours practically necessary for gravity cream. It can usually be delivered in from twenty-four to thirty-six hours from the cow, but, as it keeps well, it is frequently not shipped, in winter at least, for ten days or two weeks, and sometimes for even longer. Most cream delivered in New York is at least seventy-two hours old before it reaches the city. If there happens to be a surplus, the extra cream is kept buried in ice for days. Nearly all the cream furnished to private families is separator cream, and, though brought to the city in forty-quart cans, is put into half-pint, pint, and quart bottles before delivery. Bottling in the city is now under the regulation of the health department, and must be done in such a manner as to prevent "contamination by dust from the streets or by other impurities." Moreover there are certain regulations as to cleansing and caring for the bottles. Certain dairies, however, send their cream to the city in bottles filled and sealed while the cream is fresh. Milk bottles are prepared in the same way, and if these are carefully carried much less time is required for the cream to reach the top after delivery than when the bottles are filled just previous to delivery. The practice of supplying milk and cream in bottles is now about twenty years old, and in that time the methods have been immensely improved. When the bottling is done in a properly equipped laboratory under sanitary regulations there is no doubt that the bottles form the best and safest means of delivering the milk, but when the bottling is done in an unsuitable place, with improperly cleansed and unsterilized material, there is also no doubt that the bottling system is one of the most objectionable. In 1896 less than five million quarts, *i.e.*, less than one-sixtieth of the whole amount, came to the city in bottles, but as there are about 1,700,000 bottles in daily use in the city the immense importance of supervision of these possible infection carriers is evident. Clubs, hotels, restaurants, and ice-cream factories also get the machine cream, but usually have it supplied in cans. The great bulk of this variety is 20 to 30 pound cream, but there are prepared and shipped with greater or less regularity 15, 18, 20, 25, 30, 35, 40, 50, and even 55 pound cream. This means that the number of pounds specified of butter can be made from a forty-quart can of the cream. That this classification, however, is a commercial one of the roughest character may be seen from the accompanying analyses which have been made of ten samples of each class:

15.75	[illegible]	[illegible]	[illegible]	38.25	46.05
[illegible]	[illegible]	[illegible]	30.50	[illegible]	[illegible]
11.25	13.5	35.70	38.90	37.20	41.70
11.75	18.00	29.90	36.50	36.40	42.88
[illegible]	[illegible]	[illegible]	[illegible]	34.02	[illegible]
14.35	[illegible]	[illegible]	33.33	35.93	[illegible]

[illegible]	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]
14.35	[illegible]	[illegible]	29.93	37.40	38.23
[illegible]	[illegible]	32.15	26.95	[illegible]	38.25
[illegible]	[illegible]	[illegible]	26.85	42.35	42.99
17.85	16.95	33.83	[illegible]	38.93	[illegible]
[illegible]	[illegible]	[illegible]	[illegible]	37.59	[illegible]

As will be observed, some 20-pound cream has less fat than some 18-pound cream, and other 20-pound cream has nearly as much fat as some 25-pound cream; moreover, the 25 and 30 pound creams differ in their average fat content by only about one per cent. The inexactness of this classification, however, is probably due to the fact that there is yet no considerable well-formulated demand for a cream of a known fat content. The Walker-Gordon milk laboratory, which furnishes two classes of cream, one containing sixteen per cent. of fat and the other thirty-two per cent. of fat, has a patronage which is almost the only exception. Even the rough division specified is used almost exclusively by the wholesale dealers, and the usual reply of the retail dairy or milk men, when asked for information about the cream, is either that they have but one grade and that that is "a good cream, good enough for anybody," or, in the case of some special dairies, that they have two grades, a "light" and a "heavy" cream. The exact composition of the particular cream or creams is usually unknown to them. Every dealer knows practically how good a cream must be in appearance, that is, to sell in his neighborhood; and he secures from the wholesale dealer a cream having about that appearance. Whatever the character of the cream, the retail price at any of the fifty-five hundred milk stores in New York is nearly the same, about five times as much as milk, *i.e.*, it is approximately forty cents a quart through much of the city, though seventy-five cents and ten cents per quart have been noted as extremes. The wholesale rates for ordinary cream vary with the price of milk from $4.50 to $6.00 for a forty-quart can. Heavy (40-pound) cream varies from $11.00 to $13.00 per can. Dr. Van Slyke, chemist of the New York Agricultural Experiment Station, has pointed out that everywhere in the State "the sale of cream is absolutely without control or supervision, except that the agricultural law defines pure cream as cream taken from unadulterated milk. Anything passes as cream which the consumer is willing to accept, whether it contains ten, fifteen, twenty, or twenty-five per cent. of fat."

Such is the present state of the cream supply, but not a necessary state. Any grade of cream required may be easily furnished with a centrifugal machine, simply by supplying the milk to the separator at a greater or less rate of speed. The amount of fat in the milk used for the cream must be known. For example, if the milk contains four per cent. of fat and a twenty-pound cream is desired, as many quarts of the four per cent. milk must be used in the separator as four is contained in twenty—that is, five. Fourteen cans of average milk are necessary to make one can of fifty-pound cream, twelve cans of milk to make one of forty-pound cream, and so on.

I cannot forbear saying a word here of the by-product in the production of cream, the skimmed milk. This has the following average composition: Water, 90.34; fat, 0.15; sugar, 3.98; casein, 4.80; salts, 0.78. At present it is used largely in the manufacture of skim-milk cheese, and also to some extent in feeding calves and pigs, and is sold to farmers at ten cents for a forty-quart can. An immense amount of this nutritious and readily digestible food could probably be sold in New York at a price which would make it one of the cheapest of good foods were it not for the clause in the sanitary code which says that "no milk which has been . . . changed in any respect . . . by

the removal of cream shall be brought into, held, kept, or offered for sale at any place in the city of New York." This evidently forbids the use of milk freed from fat by a milk laboratory. That skimmed milk may be sold by unscrupulous dealers as whole milk hardly constitutes sufficient reason for prohibiting its sale for what it is.

The factors necessary for the production of cream of definite fat contents are a skilled dairyman, an efficient separator, milk of uniform composition (to obtain this the day's milk supply must be put in a vat, thoroughly mixed, and its composition tested), and a Babcock tester for the rapid determination of the amount of fat. This last instrument is in brief a centrifugal apparatus containing a bottle in which the cream to be tested in placed together with sufficient sulphuric acid to set free the entire fat content. In less than ten minutes the fat can be all brought into the long neck of the bottle and its total amount read on an attached scale. At my suggestion the Sheffield Farms Dairy Company kindly undertook to produce for a week a cream which should contain uniformly forty per cent. of fat. This cream was made daily; a specimen was analyzed the following day by Dr. Lederle and the following list of percentages resulted: 41.20, 38.50, 40.50, 39.00, 40.80, 38.50, 41.00, 40.00. No specimen was more than one and one half per cent. from the prescribed forty per cent., and an error of that size in cream of that grade may be safely neglected.

Accepting then this as a demonstration that cream of a uniform composition can be produced, and noting the statement of Mr. Halsey, the president of the company, that it can be produced without greatly increased cost, it remains to be observed that cream of one composition does not always have the same appearance. Cream thickens with age, and it is therefore a very frequent practice, especially in cold weather, to hold back cream from delivery for several days that it may appear richer. This increase in thickness of the cream is due to bacterial growth. Russell reports that, in seven samples of cream taken when the cream was from six to eighteen hours old, the average content was a little over a million bacteria per cubic centimetre; and that in fifteen samples taken when the cream was from thirty to forty-two hours old, the average content was somewhat over nine million bacteria per cubic centimetre. Still it should be added that the work of the last few years has emphasized the fact that the number of bacteria present in milk is of very little significance. The widest possible variations in the numbers seem to be found under almost identical conditions. The difficulties in the way of obtaining from the cow milk without bacterial contamination are extremely great and practically insurmountable. The milk even when first drawn from the cow usually contains bacteria, probably on account of the ease with which the milk is contaminated in the milk duct. On the other hand the variety even of non-pathogenic bacteria is all-important. Considerably over two hundred distinct types of ordinary milk bacteria have been described in literature up to the present time. It has been shown, for example, that it is to the growth of a few well-studied species that the aroma and flavor desirable in cream and butter are due, and it is not less true that the disagreeable flavor and odor occasionally noted in cream are due to other bacteria. Conn's bacillus No. 41 has been shown to give butter the flavor which is known among experts as that of "June butter." The effect of sterilization or pasteurization is to make a cream which is thinner in appearance than unsterilized or unpasteurized cream. This effect has been regarded as a detriment, and at the Wisconsin Agricultural Station it has been shown that cream can be artificially thickened by adding a solution of cane sugar in lime water, that is a sucrate of lime, "viscogen" so-called, with, it is said, no injurious results to the cream.

The physical action of separation is of value in diminishing the number of bacteria in cream, for a varying proportion is caught in the slime of the separator. Many other bacteria, however, are carried over into the skimmed milk, and, according to Dr. Moore, especially into the cream. For example, examination of milk artificially infected with bacilli of tuberculosis, and then separated, showing that in 16 per cent. of the preparations of the skimmed milk, and in all of those of the cream, tubercle bacilli were found. They were also more numerous in the preparations made from the cream than in those made from the milk, and this result was always the same, without regard to the rapidity of revolutions of the separator. It has been shown too along the same lines that butter may serve to carry typhoid fever, tuberculosis, and certain other germ diseases. Separation, therefore, is not an adequate means of obtaining a sterile cream.

That, in the absence of the few desirable bacteria, it is a distinct advantage to have cream as nearly sterile as is possible without any alteration in its physical characteristics, hardly needs argument. Sterilization by any method now in use is known to change the character of cream so as to make it unsuitable for many purposes, notably for use in infant feeding. That pasteurization probably modifies the milk somewhat is shown by the fact that the coagulum produced by hydrochloric acid is different in character in pasteurized milk from that in fresh milk. There should, however, in pasteurized milk be no "cooked" taste. The temperature at which this taste appears is not a definite and distinct point, however, but varies somewhat with the treatment given to the fluid: moreover a marked cooked taste may be perceptible immediately after heating, and then disappear when the milk is cooled. Nevertheless, milk heated above 70 C. usually has a slight cooked taste. That pasteurization as usually performed leaves a considerable number of bacteria is shown by Russell, who found as an average of fifty-eight samples of unpasteurized twenty-five-per-cent. cream 8,700,000 bacteria per cubic centimetre, and in the same pasteurized an average of 24,250 bacteria per cubic centimetre: he has isolated fifteen species of bacteria from pasteurized milk and cream, numerous enough to make it certain that they were derived from the milk. Of these only six predominated; and by a study of these he came to the conclusion that to a large extent the lactic-acid bacteria are destroyed by pasteurization, that half of the ordinary forms present seem to have no effect on the physical character of the culture medium, and that the bulk of the remainder belong to the rennet-forming bacteria. Bacteriological study of pasteurized cream has shown that old cream, which is more apt to have spore-bearing germs, is not at all well suited for pasteurization. It has sometimes happened, for instance, that cream pasteurized on Monday has failed to keep as long as that pasteurized on the Saturday previous. This was due of course to the large number of spores present in the older cream. The cost of pasteurizing milk on a large scale is less than that of sterilizing the milk; and, as the result of a careful study of the subject at the Wisconsin Agricultural Station, Russell says that the actual cost of pasteurizing cream is merely nominal, although it varies somewhat under different conditions. Where a business of any magnitude is carried on, the cost of operating the plant could not, under ordinary conditions, be more at most than a very few cents a gallon.

To the energy and interest of Dr. H. L. Coit, of Newark, is due the supply to that city of what is called "certified milk;" a committee of physicians stated

formally certain conditions, on the acceptance and the proper carrying out of which by a milk dealer under inspection they were willing to allow him to mark the milk "certified," and to furnish a certificate, signed by this committee, as to the character of the milk. Would it not be possible here in New York to establish a similar process of certification for cream; that is, might not a committee of physicians lay down certain conditions of production, of analysis, and of care, under which they would permit the use of the name "certified cream"? Collier in a comparative study of the profits derived from selling milk, butter, cheese, and cream finds that selling cream is by far the most profitable; and points out that the reason is that the consumption of cream is comparatively small, consumers regarding it as a great luxury, and that they are not aware of the fact that it would often be more economical to purchase milk and raise their own cream. It may be mentioned that the milk experts have for some time advocated the sale of both milk and cream on the basis of the fat content; then a three-per-cent. milk, for example, would have a certain price, a three and one-half per cent. a higher price, a four-per-cent. still higher; while there might well be grades of milk fortified by addition of cream which should be six per cent., seven per cent., and so on. Then every person selling milk at retail should be compelled by law to place in conspicuous figures on each can or vessel, in or from which milk is sold, the percentage of fat in the milk; he should be required to guarantee this, and be prosecuted if an examination showed the milk to be below the guarantee. Purchase of milk and cream on this basis of fat content is actually carried out at the present time in many cheese factories and creameries.

The main propositions of this paper are, in brief:

1. Cream in this city is at present milk containing an amount of fat greater than five or six per cent.

2. Cream containing any desired percentage of fat could be regularly furnished without material increase in cost.

3. Cream is now usually old when it reaches the consumer.

4. Cream as fresh as milk could be furnished to the consumer.

5. Cream is now usually so laden with spore-bearing germs at delivery that pasteurization is to a great extent ineffectual.

6. Cream could be pasteurized while fresh at the dairy at little cost.

7. An easy means of securing a supply of cream of known composition, age, and bacterial condition would be certification by a responsible body.

THE CREPITANT RÂLE AN INTRAPLEURAL SOUND.

By F. A. BURRALL, M.D.,

[redacted]

[redacted]

In the MEDICAL RECORD, of June 5th, ult., is a clear and instructive article by Dr. Louis H. Jones, of Atlanta, on the seat of the crepitant or vesicular râle, which is worthy of careful reading.

I think this is especially true, because, notwithstanding all that has been said and written concerning this râle, the method of its production still remains somewhat unsettled. Not very long since, at a meeting of the Academy of Medicine, one of the speakers referred to the crepitant râle as diagnostic of pneumonia, which showed that this view is still existent. The older teachings were that the crepitant râle was pathognomonic of pneumonia, but it seems to me that an impartial examiner of Dr. Leaming's writings on this subject must arrive at an entirely opposite conclusion. My friend, Dr. J. H. Anderson, first called my attention, several years ago, to Dr. Leaming's views. They were the result of careful and continuous study, and have been of the greatest service to me in my practice. About the time when I first heard of them I had been treating a class of cases in which the febrile reaction and constitutional disturbance were not very marked, in which the crepitant râle was present, yet they were not pneumonia and would run their course in about ten days.

I thought them, yet in an unsatisfied way, to be subacute œdemas of the lungs, but when in the light of Leaming's teachings I discovered plastic exudation with intrapleuritic râles the diagnosis cleared up. Since that time I have seen fewer cases of pneumonia, and can conceive one reason why this should be so, with a more satisfactory knowledge of the mechanism of the crepitant râle. I cannot but think also that one reason why I found so few of my cases of influenza complicated with pneumonia must be that the teachings of Leaming led me to place the vesicular râle of "acute epidemic bronchial catarrh," or influenza, within the pleural cavity instead of in the lung. My own experience, which, like that of most general practitioners, has embraced many cases of the grippe during recent years, leads me to believe that if the elements of rest, with early and steady support, as well as careful avoidance of hepatic obstruction (a term used for want of a better), be avoided, the grippe is not very likely to run into pneumonia.

Dr. Leaming was very confident of the correctness of his views and I have often talked with him upon the subject.

With regard to the diagnosis of this râle and its situation, Dr. Jones writes that this sound "lacks the element of distance. While not a loud sound, yet the ear placed in contact with the naked chest wall will recognize that it hears a sound which is immediately beneath the surface and not produced deep down in the lung tissue."

I would suggest that additional aids in the study of the vesicular râle are found in the phenomena of superficial dulness with light percussion over an area in which the râle is audible and deep resonance with harder percussion over the same area. A reasonable explanation is that the superficial dulness proceeds from percussion over the layer of plastic exudation, while harder percussion over a lung not engorged develops a resonant sound.

It is very desirable that, with our present knowledge on this subject and our improved methods of investigation, the mechanism of the crepitant or vesicular râle should be fully and clearly understood.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

New York, September 11, 1897.

THE REGULATION OF MARRIAGE.

DR. E. T. RULISON read a paper on this subject before the Academy of Medicine of Buffalo, last winter, in which he gave a brief history of marriage and called attention to the Jewish canonical laws on the subject of the marriage contract. He showed that to the care exercised in marriage is due the constant and wonderful progress that this race has made and its prominence commercially, politically, and intellectually. The Greeks selected their wives with a view to the health and vigor of their children. Parentage is too serious a question to be left to chance, as is now, at least in this country, usually the case. Any one who is in doubt as to the influence of heredity should read Ribot's work on this subject. Darwin says: "Man scans with scrupulous care the character and pedigree of his horses, cattle, and dogs before mating them, but when it comes to his own marriage he rarely or never takes any such care." Both sexes ought to refrain from marriage if they are in any marked degree inferior in mind or body; but such hopes are Utopian and will never be realized until the laws of heredity are understood.

The low, diseased, and vicious marry early and beget a numerous progeny, while the thrifty usually marry later and have fewer children. With savages the weak in mind and body are soon eliminated, but we do all in our power to prevent this elimination by building asylums and hospitals, and using every effort to prolong their lives. Dr. Rulison gives alarming statistics as to the increase of the criminal, insane, and defective classes, and shows the great expense of their maintenance. Simply to name inebriety, tuberculosis, syphilis, idiocy, and epilepsy is to remind us of the fact that the burden we are carrying is almost overwhelming. "You who were fortunately born must be the keeper of your dangerous though perhaps unfortunate brother man, or he will overpower and ruin you." It should be the first duty of the State or nation to protect the lives of future generations, as well as the lives and property of those now living. The law protects us against scarlet fever, diphtheria, and small-pox; why not, he asks, against ill-advised marriages, the results of which are almost as serious? Education has done nothing for us in this direction so far. Wealth and social position are important factors in making up the sum of human happiness, but how insignificant when compared with health! "If we are to be left perfectly free to follow our own impulses, or ambitious promptings to attain wealth or social position through matrimony, regardless of physical consequences, then I can see no relief for the great majority of our people, but perpetual ill-health and misery." Our schools, pulpits, and periodicals might enlighten our boys and girls, might teach them that parentage is the prime object of marriage, and prepare them to assume the responsibility.

In Brazil, it is said, there is a self-imposed law among the higher classes in relation to marriage. The man about to marry is compelled to furnish a certificate from one or more physicians to the effect that he is free from diseases of a certain character and from signs of diseases that could be transmitted to offspring. The physician consulted must testify that, as far as he can learn, the union is in accord with the laws of sanitation. At a recent woman's congress held in Paris resolutions were adopted to the effect that all families must secure certificates of health from intending sons-in-law in order to guard the daughters of the Republic from risk and to prevent hereditary maladies in the fathers of a later generation.

"As society is at present constituted and controlled, the unhealthy and vicious class is increasing more rapidly than the desirable one. In the days of Malthus the danger lay in the population increasing more rapidly than the means of subsistence. This danger no longer threatens, but a more serious one in the survival and overwhelming increase of imperfect physical and mental beings."

Dr. Rulison suggests that a medical staff be appointed to examine all boys and girls from twelve to fifteen years of age, relative to their physical condition and family history and that records be kept. He suggests three classes: (*a*) Those being physically and mentally sound, of good habits, and having no history of hereditary disease for at least three preceding generations. (*b*) Those having the same qualifications but with a family history extending to the grandparents only. (*c*) All those not included in classes *a* and (*b*). No one should be allowed to marry outside of the class to which he or she belongs. This would tend to make classes (*a*) and (*b*) continually stronger and better. Class (*c*) would at first predominate, but, if those included in it were not permitted to marry outside of their class, nature in a few generations would solve the problem by eliminating them.

Perhaps the time will come, in the course of the evolution of the human race, when methods such as those suggested by the author can be put in practice. But by the time mankind is ready to adopt this marriage regulation, disease will doubtless have been banished by other means, so that the course of true love will continue after the present fashion, uninterrupted by committees of unromantic and meddlesome doctors.

The Sale of Cocaine, except upon the written prescription of a legally qualified physician or dentist, has been forbidden by an act of the Colorado legislature.

UNUSUAL MODES OF POISONING WITH LEAD.

In view of the manifold and obscure channels through which lead may enter the system, as well as the difficulty oftentimes of referring the symptoms of intoxication to their proper cause, especially when a knowledge of contact with the metal is to be acquired only by direct and searching inquiry, the report by Pel, of Amsterdam (*Centralblatt für innere Medicin*, June 12, 1897), of three uncommon modes of poisoning with lead is not without interest and importance. The first case occcurred in a shoemaker, nineteen years old, who suffered from pain in the testicles, which was increased by walking. The pain was constant, though marked by exacerbations. In the course of three months pain appeared also in the right shoulder, with corresponding amelioration of that in the testicles. For several days there had also been pain in the hypogastrium. The bowels were constipated; the appetite was impaired. The patient was emaciated and sallow. Examination of the gums disclosed the presence of a blue line. There was at times difficulty of micturition; the urine contained urobilin and hæmatoporphyrin. Under treatment with opium, purgatives, and potassium iodide, improvement soon followed. On inquiry it was learned that the patient had been employed in the manufacture of shoes for the government, using tinned nails, in the preparation of which lead entered. For convenience' sake, the man held the nails in his mouth, from which he removed them one by one as required. It was not known that other men employed in the same factory exhibited symptoms of lead-poisoning. The neuralgic pains were considered to be of toxic nature.

The second case occurred in a cigarmaker, forty-four years old, who for fifteen months had suffered from rheumatic pains in the arms, legs, back and hypogastrium, and from headache. The man was nervous and sleepless and constantly languid and tired. The bowels were torpid, the appetite was poor, the complexion sallow, and the nutrition impaired. There was a blue line at the margin of the gums and the urine contained urobilin and hæmatoporphyrin. In this case it was learned that the patient in the process of making the cigars rolled them upon a board covered with a tin plate, in the composition of which lead entered. Upon this plate also the cigars were cut with a knife which the man was in the habit of holding in his mouth.

The third case occurred in a man, twenty-nine years old, who had been employed for fifteen years in embedding diamonds in a warmed lead mass, manipulating this with the fingers moistened with saliva. On account of impaired eyesight the man was compelled to give up this work and seek employment elsewhere, becoming a clerk in a bakery. In the course of five months symptoms of acute lead poisoning made their appearance—nausea, vomiting, colic, constipation, increased arterial tension, typical urinary phenomena, and a blue line on the gums. Cases of similar kind have been previously observed in Holland, though rarely.

These cases serve to illustrate some of the less common modes of poisoning with lead, and their recital should stimulate the clinician always to the most searching inquiry in the determination of the origin and nature of apparently simple and uncomplicated cases, as well as those of greater complexity and obscurity.

THE POPE ON WHAT TO EAT.

The Pope in his extreme old age has been giving some sound advice in the matter of food. Although the dietary set before us by the Pope is not an especially luxurious one, still there are many persons who would be only too glad to be able to follow his advice. In fact it will strike most persons who read it that the Pope is not a bad judge of what is good for him, and is himself a proof of the efficiency of his maxims. He writes: "Pay attention before all to cleanliness, that the table appointments are spotless, glass bright, napery immaculate, that from the cellar comes the purest wine of the Albanian Hills, which exhilarates the spirit and drives away trouble: but do not trust Bacchus, so do not be sparing in diluting wine with water; obtain from healthy grain well cooked bread, eat sparingly of chicken, lamb, and beef which are most nourishing to the body; meat should be tender without abundant sauces or root vegetables, which spoil it; fresh fruits are excellent whether raw or slightly cooked: an abundant quantity of foaming milk, it nourishes infants and assists old age; also honey, celestial gift, but this Ibleo nectar [from Mount Ibla in Sicily] use frugally; add to this the sweet herbs and fresh vegetables that the garden supplies; add ripe fruit according to the season, and especially tender apples, which with their pink tints brighten the banquet; lastly comes the drink, which in hard seeds fertile Moka sends you, softly sipping the black liquor that comforts the heart." From the foregoing it would appear that Leo is a disciple of Horace. Certainly the menu has quite an Horatian flavor.

A Proposed College for Medical Missionaries.—The guild of St. Luke, in London, has under consideration a proposal to establish a college of St. Luke for men training as medical missionaries in connection with the Church of England. The *British Medical Journal* says that it is proposed that the institution should be purely residential. Its principal would be a medical man, and it would have a chaplain, while the students would receive their medical education at the London medical schools. Those who intended to become medical missionaries after qualification would be supported by the guild or other society, entirely or in part, but other students would also be received. At a recent meeting a discussion took place on the subject, and the hope was expressed that such a residential college would be the means of providing suitable men for many medical posts in connection with mission stations which it had hitherto been difficult to fill.

News of the Week.

The Surgeon-General of the Navy.—The term of service of Surgeon-General Tryon has expired, and it is expected that the announcement of the appointment of his successor by the President will soon be made. Dr. Tryon has been thirty-five years in the medical department of the navy, and has an enviable record for efficient service at sea and on shore. It is to be hoped that the President will see his way to reappointing Dr. Tryon to the post which he has filled with such credit to himself and benefit to the service.

Yellow Fever on the Gulf Coast.—A fever which has been prevailing for some weeks at Ocean Springs, Miss., on the Bay of Biloxi, and which was thought to be dengue, has been pronounced yellow fever. About two weeks ago the health authorities made an investigation. There had been several hundred cases then, but very few deaths, and a board of experts declared the disease dengue fever. The death rate increased, however, and the symptoms looked more like those of yellow fever; the alarm now became so great that the health authorities again convened, and, after a searching investigation, pronounced the disease yellow fever. It seems probable that there was first an epidemic of dengue and that the yellow fever was brought in later, but passed unobserved for a time in the midst of the cases of the prevailing fever. The Marine Hospital service has sent several surgeons to the place to examine the cases and to take the necessary precautions if the diagnosis of the State health authorities should be confirmed.

The Tri-State Medical Society of Alabama, Georgia, and Tennessee.—The ninth annual meeting of this society will be held in the senate chamber of the State Capitol, Nashville, Tenn., Tuesday, Wednesday, and Thursday, October 12, 13, and 14, 1897. The secretary of the society is Dr. Frank Trester Smith, of Chattanooga, Tenn.; the president, Dr. W. F. Westmoreland, of Atlanta, Ga.; and the chairman of the committee of arrangements, Dr. W. D. Haggard, Jr., of Nashville, Tenn.

A Collective Investigation of Infantile Scorbutus.—The American Pediatric Society is making a collective investigation of infantile scurvy as occurring in North America, and earnestly requests the co-operation of physicians, through their sending of reports of cases, whether these have already been published or not. No case will be used in such a way as to interfere with its subsequent publication by the observer. Blanks containing questions to be filled out will be furnished on application to any one of the committee. A final printed report of the investigation will be sent to those furnishing cases. The committee is composed of Drs. J. P. Crozer Griffith, chairman, 123 South Eighteenth Street, Philadelphia; William D. Booker, 853 Park Avenue, Baltimore; Charles G. Jennings, 457 Jefferson Avenue, Detroit; Augustus Caillé, 753 Madison Avenue, New York; and J. Lovett Morse, 317 Marlboro Street, Boston.

The Fate of the Idiot.—The *Journal of the American Medical Association* has in a recent issue a long and unconvincing argument in support of its proposition to kill all idiots. This is, of course, a very easy solution of the problem of what to do with these poor creatures, and the same remedy would be extremely efficacious in the case of the incurably insane, the crippled, sufferers from cancer, the blind, the aged, and all who are more or less of a trouble for society to take care of. We trust, however, this is not to be regarded as an opinion stamped with the approval of the trustees or any other officers of the American Medical Association.

The British Medical Association.—At the closing session, on Friday of last week, Dr. Saundby, president of the British Medical Council, introduced a motion recommending the election of the Governor-General of Canada, and Lord Strathcona and Mount Royal, to honorary membership in the association. Dr. Roddick, the retiring president, introduced a resolution indorsing the scheme for the organization of a system of district nursing in the isolated portions of Canada. He remarked that many people refused to emigrate to Canada on account of the great distance they would be, particularly in the Northwest, from nursing and medical assistance. It was contemplated to establish an order of nurses which would work throughout the dominion, and the name Victorian Order of Nurses had been suggested by the Countess of Aberdeen, with whom the scheme originated. On Saturday the members of the association went on an excursion to Ottawa, where they were entertained by the local medical profession, and after a luncheon were shown through the Parliament buildings and taken about the city on electric cars.

Tuberculosis at an Agricultural College.—The board of regents of the Kansas State Agricultural College at Manhattan has discovered that many of the cattle, sheep, and hogs kept on the college farm are infected with tuberculosis. Several of the attendants who have been employed at the stables are seriously ill, and one who has had more direct charge of the cattle is not expected to live, having been suffering with the disease for several months. Others connected with the college, but who have not been brought into direct contact with the diseased cattle, are also tuberculous, and it is thought that they may have become infected through drinking the milk of diseased cows.

Dr. Luys, of Paris, died recently at the age of sixty-seven years. He was an extreme believer in the wonders of hypnotism, believing that he could narcotize people by holding near the brain a closed vial containing morphine. Some years ago these cases were investigated by Mr. Ernest Hart, and it was shown that the subjects wilfully deceived the too credulous experimenter.

A Woman's Medical Society in Europe.—There are between thirty-five and forty medical women in Switzerland, and a number of them recently got together and founded a club of female physicians, which is said to be the first of its kind in Europe.

Diarrhœa in London.—The prevalence of and mortality from diarrhœa in London among children under five years of age are exciting much comment. The death rate from this cause is higher than it has been for very many years. By many people it is thought to be due in the poorer portions of the great city to defective drainage, as in children so young the cause can hardly be the one usually given—the consumption of unripe fruit. It really seems that something must be wrong in the sanitary conditions of London, for, in addition to diarrhœa, diphtheria is more rampant than for some time.

The Johns Hopkins University has recently been beaten in a suit against the receivers of the Baltimore and Ohio Railroad, by which it endeavored to establish its claim to be a preferred creditor. The court has decided that such a claim is untenable, and the university will suffer in consequence a considerable reduction in its income.

Honors for Professor v. Kolliker.—The Imperial Leopold-Carolina Academy of German Scientists of Halle has awarded the gold Comenius medal to Professor von Kölliker, of Würzburg, who recently celebrated the completion of his eightieth year and the jubilee of his appointment as professor.

The American Academy of Railway Surgeons.—The next annual meeting of this society will be held in Chicago, October 6, 7, and 8, 1897.

American Electro-Therapeutic Association.—The next annual meeting of this association will be held at Harrisburg, Pa., September 21, 22, and 23, 1897. The preliminary programme contains a list of nineteen papers on a wide variety of subjects.

Typhoid Fever is prevailing to an alarming extent in several places in Germany. In many of the small epidemics the milk supply has been incriminated, and the Berlin health authorities have issued a special warning to the public against the use of unboiled milk.

Cruelty to Convicts.—An investigation into the condition of the convicts in Georgia has revealed the existence of many shocking abuses, both of cruelty and flagrant disregard of sanitary provisions, occurring in private camps, where misdemeanor convicts were leased to individuals in violation of law. Of seventeen hundred and ninety-two misdemeanor convicts, about four hundred are thus hired. The rate of mortality in private camps is about double that in the public camps. In the private camps the law requiring a daily record of the conduct of each convict as a basis for the good-conduct allowance of four days a month is ignored. In one camp thirty negroes and one white convict slept chained together in a close unventilated room, only fifteen by seventeen feet, with the window nailed up. In another camp, at his first visit the inspector found forty-six negroes and fifteen whites sleeping in a room nineteen feet square and less than eight feet high. It is said that the governor of the State contemplates pardoning all of the convicts in private camps, as the only way in which he can rescue them before the expiration of their terms.

Failure of Koch's Rinderpest Remedy.—The government of the Cape of Good Hope is now regretting the money spent in securing Koch to elaborate a protective serum for use against the rinderpest. The undertaking has ended in absolute failure, for the inoculation treatment has had no effect in preventing the cattle from dying of the disease. It is said that Koch is about to return to South Africa to renew his experiments and try once more to make an effective serum. The *Medical Press* says that the Cape government, "has not found that its introduction of a German professor into the colony has had any other effect than that of costing it a large sum of money. Perhaps, upon the next occasion that some official bacteriological investigations are required, it will bear in mind that science made in Germany is no better than science made elsewhere," and, our contemporary might have added, it has of late acquired a decidedly commercial character.

The Study of Apparent Death.—A committee has been formed in Naples for the study of the question of apparent death. The president is Dr. Oscar Giacchi, and the members are Drs. G. Albertolli, F. Bonelli, E. Chiaisio, S. Lanza, F. Conti, L. Lombar, and P. Vandoni, and Miss Elizabeth Berkeley-Barter. The secretaries of the committee are Dr. F. Bonelli and Signor C. Gallo.

The Fatal Bargain Counter.—A woman was killed recently in London in the crush at a bargain sale. The crowd of women was so large and so disorderly that it required the services of twenty-two policemen to hold it in check. The verdict of the coroner's jury was that the woman "died from syncope caused by the exertion and excitement of getting into a bargain sale, and that such death was due to natural causes."

Murders by the Brute Creation in India.—During the year 1896, according to the official statistics just published, 1,133 persons in India died from the effects of serpent bites, and 291 were killed by tigers and other wild animals. The figures are much below those for the preceding years.

Obituary Notes.—Dr. George W. Vogler, of Philadelphia, died at Este's Park, Col., on August 26th, in his forty-second year. He was graduated from the medical department of the University of Pennsylvania in 1876, and was subsequently resident physician in the German and Philadelphia hospitals. Later he became consulting physician to the German Hospital, and was chief of the out-patient department for diseases of women.—Dr. William Brodie died suddenly at Forest Grove, Pa., on September 3d, of nephritis, at the age of forty-two years. He was born in Philadelphia, and was graduated from the medical department of the University of Pennsylvania. After a year's practice in Philadelphia he removed to Pineville, and subsequently to Forest Grove.—Dr. H. R. O'Conner, of Pittsburg, Pa., died at Charles River, Mass., on August 31st. He had been engaged in practice for more than twenty-five years, and was one of the physicians to the Southside Hospital and also a pension examiner.

Society Reports.

BRITISH MEDICAL ASSOCIATION.

Sixty-Fifth Annual Meeting, Held at Montreal, Canada, August 31, September 1, 2, 3, 1897.

Special Report for the Medical Record.

GENERAL SESSIONS.

(Continued from page 340.)

Third Day—Thursday, September 2d.

THE PRESIDENT called the meeting to order at 3 P.M.

The Surgeon of Old in War. — The address in surgery was delivered by MR. T. MITCHELL BANKS, of Liverpool (see page 340).

At the conclusion of the address a hearty vote of thanks was tendered Mr. Banks for his instructive discourse.

The meeting then adjourned, a large number of members visiting the General Hospital, where the cornerstone of the new Nurse's Home was laid by Lord Lister at 4:30 P.M. The annual banquet of the British Medical Association was held in the evening.

Fourth Day—Friday, September 3d.

The meeting was called to order by the president at the usual hour.

Preventive Medicine in the City of New York. —DR. HERMANN M. BIGGS, of New York, then delivered the address in public medicine. The speaker acknowledged his appreciation of the honor conferred upon him by the invitation to deliver the address on public medicine, but he interpreted that invitation as a tribute to the work of the health department of New York City, with which he had been so long connected, and regarded it as a command from the council to select for the subject of his address the discussion of some of the measures which have more particularly distinguished the work of the New York health department, rather than the consideration of any general topic of public medicine. It has been the custom of sanitarians of all nations to look to England for guidance and direction in matters connected with public health, and the low mortality statistics, especially from zymotic diseases, in England testify in no uncertain language to the value of English sanitary methods and the efficiency of their execution. The advances in sanitation in Great Britain have preceded those in every other country.

In the United States there is no national board of health, each State having its own health board and sanitary laws, and consequently there is no uniformity in regulations and methods. Speaking broadly, in the rural districts and in the smaller towns the sanitary methods are crude, while in many of the large cities there is an enlightened and progressive policy to be found, equal to that in any of the great cities of the world. New York may be taken as a type of the best conditions and methods of sanitary work to be found among the greater cities of the United States, and the speaker said that he would confine himself, therefore, to the discussion of the sanitary work in New York City.

The health department of New York City is an entirely independent sanitary organization, not being subject even to the jurisdiction of the State board of health. The jurisdiction of the board extends over the whole city, containing at present about two million population; and in 1898 a similar board, increased to five members, will have jurisdiction over Greater New York, with a population of three million two hundred and fifty thousand. Ordinarily the duties of sanitary authorities relating to the infectious diseases are limited to the inspection of reported cases of only a few of the infectious diseases, the removal of patients to hospitals when required, and the subsequent disinfection of the premises. In New York City, however, all matters connected with the scientific investigation, diagnosis, care, or sanitary supervision in every way of the infectious diseases are regarded by the board of health as properly coming within its province.

The Bacteriological Laboratory.—The first important departure in New York City from the older methods was made in 1892, by the establishment of a bacteriological laboratory, this being the first bacteriological laboratory ever established under municipal control. Ordinarily designed to afford facilities for the bacteriological diagnosis of Asiatic cholera and for the investigation of questions relating to disinfection, the scope of its work was soon extended to include the bacteriological diagnosis of diphtheria. The investigations of the New York City health department relating to diphtheria laid the foundation of municipal bacteriological laboratories and made them necessary to the proper conduct of sanitary work. In October, 1894, investigations in connection with the production of diphtheria antitoxin were begun, and in December of that year a special annual appropriation (antitoxin fund) of $30,500 was made by the city authorities for the prosecution of this work. The special antitoxin fund made possible the establishment of a research bacteriological laboratory devoted to the production of diphtheria antitoxin and other bacteriological products, and to general experimental investigations in relation to the infectious diseases. In 1896 arrangements were completed for placing at the command of the physicians of New York City Widal's test for the diagnosis of typhoid fever, and recently arrangements have also been made for the administration of Pasteur's treatment for the prevention of rabies. A special laboratory and stable are devoted to the production of bovine vaccine virus, and this is freely distributed and vaccination is performed free of charge by the medical officers of the department.

Every case of contagious disease reported to the department is inspected by the medical inspectors of the district in which it occurs, and when necessary such cases are removed to the department hospitals. Disinfection is then performed and is compulsory in every case, all infected materials being taken to the disinfection station for destruction or disinfection by steam. The work of inspection is carried on by a number of different corps of inspectors. These include the district medical inspectors, the district and special vaccinators, the inspectors for the administration of diphtheria antitoxin, the diagnosticians, the summer corps of inspectors, the medical inspectors of schools, etc. There are also a number of sanitary and food inspectors, who are not necessarily medical men, such as the inspectors of plumbing and ventilation, the sanitary police, the inspectors of offensive trades, the inspectors of meat, fish, milk, etc., and the inspectors of mercantile establishments—these last having under their charge the regulations as to the employment of women and children in such establishments. Besides these, there are veterinary inspectors, who have the supervision of the application of the tuberculin test for the diagnosis of tuberculosis in cattle and the diagnosis of other infectious diseases in cattle and horses.

Dr. Biggs then described in detail the method of procedure followed by the officers of the health department when the existence of a case of diphtheria comes to their knowledge.

The Prevention of Tuberculosis. — The speaker then explained the attitude assumed by the health department of New York City toward pulmonary tuber-

culosis, and recounted the measures adopted for its prevention. The health board first began an educational campaign in relation to the causation and prevention of tuberculosis in 1889, and leaflets based on a communication on this subject, giving the essential facts as to the nature of this disease, were widely distributed. In 1893 it was determined to institute more comprehensive measures for the prevention of this disease. The measures then adopted required notification of all cases of pulmonary tuberculosis occurring in public institutions, and requested reports of cases occurring in the practice of private physicians; they also included arrangements for the bacteriological examination of sputum; the inspection of all reported cases in tenement houses, lodging-houses, hotels, and boarding-houses, and the instruction of the patients and their families as to the nature of the disease and the means to be taken for its prevention; the inspection of the premises in all instances where deaths were reported as due to tuberculosis, and the issuing of orders, where it was deemed necessary, upon the owners of apartments which had been occupied by consumptives and vacated by death or removal, requiring that such apartments be thoroughly renovated by painting, papering, or kalsomining, before they were again occupied; and the education of the public, by wider and more comprehensive methods, as to the nature of tuberculosis. In 1894, 4,166 cases of tuberculosis were reported; in 1895, 5,818; and in 1896, 8,334. All cases reported, so far as possible, except those in private houses, were visited or the premises where they occurred were inspected, and, in addition, the premises occupied by persons dying from tuberculosis (numbering each year nearly 6,000) were inspected and such action was taken as was considered possible and desirable. In the beginning of 1897, on the recommendation of Drs. Biggs and Prudden, the health board of New York City finally declared pulmonary tuberculosis to be "an infectious and communicable disease, dangerous to public health," and required the notification of all cases occurring in the city, in the same way as is required of cases of small-pox, scarlet fever, diphtheria, etc. The health department has also elaborated with great care methods for protecting the public, as far as possible, from infection by the meat and milk of tuberculous animals. Since 1895 no milk is allowed to be sold within the city without a permit from the health department, and before these permits are issued information must be furnished as to the source from which the milk is obtained, the number of animals, the character of the food supply, and the sanitary conditions surrounding the dairy. There are also special regulations controlling the sale of milk, and the permits may be revoked if these regulations are not complied with. All milch cows in the city are subjected to the tuberculin test, and animals found to be diseased are killed. There also exists a careful inspection of animals slaughtered for food and of all meat sent into the city, and the carcasses of those found to be tuberculous are destroyed. Most beneficial effects, the speaker said, have already resulted from the various measures instituted for the prevention of tuberculosis. Not only has there been a very material decline in the number of deaths occurring from this disease, but there has been a most gratifying increase of knowledge and intelligence among the poorest class of the population as to its nature. This increase of intelligence, and the precautions resulting from it, afford the greatest promise in the future of a persistent and still more rapid decline in the frightful mortality caused by the tuberculous diseases.

School Inspection.—Early in 1897, under the authority of a special resolution of the board of estimate, one hundred and fifty medical school inspectors were appointed and a system of medical school inspection was begun. During three months, sixty-five school days, in which this system was in operation, there were examined 63,812 children, and 4,183 were excluded from school for the following diseases: Measles, diphtheria, scarlet fever, croup, whooping-cough, mumps, contagious eye diseases, parasitic diseases of the head and body, chicken-pox, and skin diseases. This system of school inspection has thus far given most satisfactory results and promises still more for the future.

The Educational Work of the Health Department constitutes a very important feature of its usefulness. It has been the custom of the department for some years past to issue from time to time circulars of information on various topics, and especially those connected with infectious diseases—their diagnosis, treatment, or management. Some of these circulars are popular in character, very large editions being published, fifty thousand or more at a time, and are designed for general distribution, particularly among the tenement-house population. These circulars are also published by the various medical journals and by the daily papers in New York City, and thus gain a very wide circulation. They are also sent by mail or delivered by messenger to the physicians of the city. Numerous scientific bulletins have also been issued from the bacteriological laboratories, detailing the results of original investigations in connection with infectious diseases, and these bulletins are widely distributed among the profession of New York City. The value of this educational work in disseminating information in regard to the results of the latest studies in infectious diseases is incalculable, and there have been constantly exhibited in New York the most gratifying indications of the influence of the information thus distributed, on both the general public and the medical profession. The criticism has often been made, particularly in Europe, and in the earlier work of the New York City health department, that the methods proposed are impracticable. The results have shown that they are not impracticable. What has been described is not something that it is purposed to do, but it is a statement of what has been done, and the work, as briefly outlined in some of its phases, is to be considered as only introductory. It is the purpose of the health board to establish a supervision of all infectious diseases along the lines which have been thus far developed, in relation to tuberculosis and diphtheria, as rapidly as the scientific knowledge at command will make such a course possible.

Reduced Death Rate in New York City.—The final test of the efficiency of any scheme of sanitary control, Dr. Biggs continued, is found in the mortality statistics. Various factors and conditions, however, may influence these, such as density of population, nationality of the inhabitants, and physical conformation of the country. The conditions in New York City are in many respects very unfavorable. The average density of population of the larger part of New York—that is, on Manhattan Island—is greater than that of any other great city of the world. Sanitary district A of ward 11, New York City, has a population of more than 800 to the acre; ward 10, over 640 to the acre; ward 13, 540; ward 17, 430. The only localities approaching these wards in density of population is a small area in Paris, where the population is 430 to the acre; one district in Prague, with 485 to the acre; and the Whitechapel district in London, which has a population of about 300 to the acre in Spitalfields, Mile End, and Newtown, and 365 in Bethnal Green. The density and cosmopolitan character of the population of New York also render the sanitary problems presented extremely difficult of solution. Then, too, the physical conformation of Manhattan Island, which is long and very narrow, produces

overcrowding, fully three-fourths of the population living in tenement-houses, which are five, six, or more stories high, and contain from two to four or more families on each floor.

A comparison of the mean death rate for decennial periods in New York City since 1834 shows that there was an increase during the first three periods ending in 1863, and that since that date there has been a continuous and marked decline in the rate, especially in recent years. The mortality in New York rose to such a point that the inhabitants became alarmed, and in 1866 the health department as now constituted was organized. In the decennial period ending in 1843 the mean death rate was 28.03; for the period ending 1853 it had risen to 33.81; the next period, ending in 1863, it was 33.94. Since that time it has declined to 31.11 for the decennial period ending in 1873; to 26.87 for the period ending in 1883; to 25.78 for the period ending in 1893; while in the year 1894 it was 22.76; in 1895, 23.10; in 1896, 21.54; and for the first half of 1897, 19.60. The population meanwhile has increased from 312,000 in 1840 to an estimated population of 1,990,000 on July 1, 1897. The mortality rate is normally higher for the first half of the year than the second half, and it is therefore probable that the rate for 1897 will be a fraction over 19, or a diminution of twenty-five per cent. on the death rate for the decennial period ending in 1893. The largest reduction has been in the zymotic death rate, including diarrhœal diseases of children under five years, and there has been also a steady decline in the death rate from tuberculosis since 1886. A reduction in the mortality from diphtheria and croup, amounting to nearly forty per cent., has occurred since the introduction of diphtheria antitoxin with the beginning of 1895. This reduction has taken place in spite of an increase in the number of reported cases of the disease. Up to the beginning of 1895 there had been a steady increase for some years in the mortality from diphtheria and croup, and for the year 1894 the death rate was higher than that from any other single disease, excepting tuberculosis and pneumonia—pneumonia really including a number of different affections. The combined death rate from measles, scarlet fever, diphtheria, croup, small-pox, and typhoid fever has been reduced exactly one-half within ten years—the rate for 1896 for these diseases being 1.64 per 1,000 population, as contrasted with 3.26 for 1887; for 1897 it will apparently be still lower.

The government of the United States is democratic, but the sanitary measures adopted are sometimes autocratic, and the functions performed by sanitary authorities paternal in character. We are prepared when necessary to introduce and inforce, and the people are ready to accept, measures which might seem radical and arbitrary if they were not plainly designed for the public good and evidently beneficent in their effects. Even among the most ignorant of our foreign-born population, few or no indications of opposition or resentment are exhibited to the exercise of arbitrary power in sanitary matters. The public press will approve, the people are prepared to support, and the courts sustain any intelligent procedures which are evidently directed to the preservation of the public health. The belief is never aroused in any class of the population, however ignorant, that the institution or inforcement of any sanitary measure is primarily designed for the restriction of the individual freedom. There is nowhere to be found any jealousy or distrust of law and government, as such. It is therefore possible to adopt measures more arbitrary in many respects than could be adopted in most other countries, simply because our government is democratic. This gives the keynote to the attitude of the sanitary authorities of New York.

In concluding, Dr. Biggs said that there is no great city in the world to-day which, in the broad sense, is cleaner and healthier than New York. By "clean" is meant purity of the atmosphere, cleanliness of the streets, abundance and purity of the water supply, and efficiency of the sewerage system. Nowhere can there be found a fuller recognition than in the United States of England's high standard of excellence in public medicine, or a more sincere appreciation of her vast contributions to the progress of sanitary science. But she must look well to her laurels if her cities are to be kept cleaner than the great cities of the United States, or her urban population is to be healthier and happier than the same class on this side of the Atlantic.

SECTION IN MEDICINE.

First Day—Wednesday, September 1st.

On the Influences that have Determined the Progress of Medicine during the Preceding Two and a Half Centuries.—Dr. Stephen Mackenzie, of London, delivered the address of the chairman, taking this as his subject. These influences were varied, the first place in point of time and one of great importance being yielded to anatomy. Of any one influence, however, that has helped the advance of scientific study and the progress of medicine, probably the increasing perfection of the microscope has been the greatest. With each new development of this instrument a greater range has been given to our researches, and, with the assistance of chemistry, it is continuing to reveal to us fresh facts that have created new branches of science. The thermometer, again, has been of invaluable aid in the study of diseases, allowing us to measure and record the degree of fever, and to watch its progress with such a degree of accuracy as to furnish us with evidence of the greatest value in the diagnosis, prognosis, and treatment of disease. Electricity, by the laborious and complete investigations of Dubois-Reymond, has revealed to us the mode of action of nerve and muscle, that would have been impossible to obtain in any other way. Though the hopes at first entertained of its value in the treatment of diseases have not been altogether fulfilled, it is still of much service in this respect, and perhaps still more valuable as an aid in diagnosis. The ophthalmoscope, introduced by Helmholtz, has enabled us to understand diseases of the interior of the eye, which without its assistance was impossible. It has allowed the exact examination of refraction, and has revealed changes in the termination of the optic nerve, in the retina, and choroid, not only valuable in themselves, but so important in the light they throw on pathological changes occurring in the nervous system and in the body generally that the use of this instrument has become a necessity of practical medicine. The laryngoscope, perfected by Czermak, has given precision not otherwise attainable to the diagnosis and treatment of diseases of the throat, and has important bearings on general medicine in the recognition of paralysis of the muscles that move the vocal cords, in aneurism, and in disease of the central nervous system. The sphygmograph, the cardiograph, the arteriometer, and, the latest invention of this class, the sphygmometer, have enabled us to ascertain the exact condition of the circulatory system, and are of the greatest service not only in studying the problems of normal and abnormal physiology, but in the recognition of disease and its tendencies and in the influence of remedies. Nothing from the time of Harvey gave such an impetus to the study of exact medicine as the introduction or discovery of auscultation by Laennec in 1816; and, indeed, Harvey's great discovery had

little practical application in clinical medicine until its introduction. Auenbrugger had introduced percussion in 1761. Laennec had adopted it, and his discovery of auscultation, with his zeal as a morbid anatomist, enabled him to work out most of the great problems of diseases of the thorax. The knowledge thus begun has, by the labors of many workers, increased in range and accuracy down to the present time, and the diagnosis of diseases of the chest has reached a degree of precision unequalled in any other department of practical medicine. We are now able not only to recognize disease of each of the valves of the heart, but to estimate its degree and the influence of the lesion on the greater and lesser circulations, and to trace the course and effects of emboli carried along the blood stream. Our knowledge of diseases of the lungs is nearly as complete as that of the circulatory system. The speaker then reviewed the progress that had been reached in clinical medicine, dwelling especially on fevers, renal diseases, diseases of the nervous system, Addison's disease, and myxœdema.

The Symptoms and Diagnosis of Cholelithiasis.—Dr. J. E. Graham, of Toronto, read a paper with this title. He said that for the success of surgical interference in gall-stone disease it is incumbent upon the physician to make an early diagnosis so that calculi may be removed before a serious damage is done by their presence either in the gall bladder or in the large bile ducts, and before the system is irreparably injured by obstructive jaundice. Cases of gall-stone disease are often divided into two classes: those without, and those with jaundice. This is at best an artificial classification, since bile pigment may be found in the urine when calculi are situated in any part of the gall bladder or bile ducts, although its presence is much more marked when they are arrested in the hepatic or common bile duct. The symptoms are influenced very much by the length of time required for the formation of the calculi. It is generally thought that they grow very slowly, but Naunyn is of the opinion that ordinary gall stones of the soft variety may form in a few days, even in a few hours. Biliary concretions may exist in the gall bladder a number of years without producing any symptoms, at least any sufficient to lead the patient to consult a physician. They have been found in one-tenth of all post-mortem examinations and in one-fourth of all in which the subjects were elderly women. Frequently indefinite symptoms have been noticed, such as bilious headache, bilious attacks without headache, and a feeling of pressure over the stomach after certain articles of food. If a frequent and careful examination of the urine were made, bile would be found in many of these cases, especially when cholecystitis exists. This latter condition in the chronic form may end in contraction and atrophy of the gall bladder. Courvoisier has collected sixty-three such cases, in seven of which the biliary passages were not obstructed. The speaker had for a number of years a patient under observation who had xanthomata of the eyelids and who suffered from frequent attacks of biliousness but with no local sign. She died of intestinal hemorrhage and the gall bladder was found filled with calculi. Fremitus has been noticed and stones have been detected by sounding. This is not a safe procedure if cholecystitis be present. When in addition to calculi there is an invasion of pyogenic organisms, very grave symptoms rapidly supervene. Pain and tenderness over the region of the gall bladder often set in suddenly. The pain is not of the nature of colic, unless the cystic duct has been entered. Symptoms of localized peritonitis and irregular high temperature, anorexia, nausea, and vomiting come on.

The speaker saw a very interesting case of this kind. The patient, a man of full habit, was in ordinary health, when, while walking, he felt a pain in the right hypochondrium, accompanied by much tenderness in the hepatic region and tension of the right rectus. Irregular fever followed, with occasional rigor, and death took place in about six weeks. The autopsy showed the gall bladder filled with calculi, the mucous surface separated by ulceration, and pyæmic abscesses in the liver and kidneys.

Eberth's bacillus is the infective agent in some cases of cholecystitis. The amount of ectasis of gall bladder varies in different cases, and when occlusion of the cystic duct exists the distention may be very great. Biliary calculi sometimes escape into the peritoneal cavity, connective tissue, or liver; such escape into the back peritoneal cavity may occur during a paroxysm. In one case the bile flowed into the peritoneal cavity, was removed by successive tappings, and the patient recovered. In the great majority of cases of rupture, previous ulceration of the bladder wall has existed, and the calculi enter the surrounding connective tissue. When calculi pass into the cystic duct the well-known symptoms of colic supervene. This colic occurs in less than one-half of all gall-stone cases. An attack may be brought on by error in diet, emotional disturbances, active movements of the body, menstruation, confinement, or after removal of abdominal tumors, etc. Hagen has collected eighteen cases occurring during the course of typhoid fever. The seat of pain is usually in the gall-bladder region, but also in the epigastrium, left hypochondrium, right shoulder, and right inguinal—simulating appendicitis. The severity of pain depends more on the shape than on the size of the stone. Death has occurred during an attack. Potain believes acute dilatation of the right ventricle may take place, as evidenced by *bruit de galop* or pulsation in the epigastrium. This he thinks is due to a spasmodic contraction of the pulmonary capillaries and consequent obstruction of the circulation.

The diagnosis of biliary colic without jaundice is often not easily made; especially is it difficult to separate from spasmodic closure of the pylorus with painful distention of the stomach. If seen during an attack the gastric distention may be evident. Excess of free hydrochloric acid in the gastric juice points to the stomach as the seat. Rigors with fever and perspirations, especially referred to by Osler, have occasionally been observed. This condition resembles urethral fever, and probably results from toxin poisoning and does not necessarily indicate suppuration. Jaundice occurs in one-half of the cases of calculi, but the presence of bile in the urine is a valuable sign. The breaking down of calculi does not often occur. When a stone is arrested in the cystic duct the completeness of obstruction may depend on the axis of the stone, and a change of its direction may materially change the symptoms. There is no proof that calculi have origin in the cystic duct. When the calculus becomes lodged in the cystic duct the gall bladder becomes distended. If obstruction is complete the viscus becomes distended with mucus. In some cases the calculi form a ball valve, allowing the entrance but not the exit of bile. As much as ten pints of fluid has been removed from the gall bladder.

The diagnosis between a distended gall bladder and a displaced right kidney is often a matter of difficulty. The differential points are: 1. History of biliary colic. 2. Movement of tumor with respiration. 3. The lower extremity is movable, whereas the upper is fixed. 4. The kidney may be felt behind the tumor. 5. The colon lies in front of the kidney and behind the gall bladder. 6. In pyonephrosis the urine may contain pus, and in distended gall bladder bile pigment may be present.

The two following cases illustrate this difficulty of differentiation:

Case I.—The patient, a married woman, fifty-two years old, had suffered during the summer from occasional attacks of pain, together with general malaise. In October a tumor was discovered below the liver, extending downward nearly to the crest of the ilium. It was large, smooth, elastic, and tender. The right kidney was displaced, as shown by the absence of kidney dulness. Under chloroform the kidney could not be found separate from the tumor. The latter did not move with respiration, nor was the lower extremity any more movable than the upper. The urine was free from pus, but contained a small amount of bile pigment. Symptoms of suppurative fever were present. Dr. Temple operated, and found a distended, suppurative gall bladder and a stone in the cystic duct. The patient made a good recovery.

Case II.—A female patient complained of severe pain in the gall-bladder region, which was accompanied by swelling below the margin of the ninth and tenth ribs. The pain occurred irregularly at intervals of weeks or months, and was nearly always relieved by pressure over this region. The tumor, which was thought to be a distended gall bladder, was found to be a distended cystic kidney. The urine was negative. The length of time, eight years, during which the patient suffered from the pains should have decided against a distended gall bladder. The operation was followed by recovery.

When the calculus has passed through the cystic duct, it usually finds its way without difficulty until obstructed by the narrow duodenal outlet. In many cases, however, it is found in different parts of the canal, but near the outlet in thirty-five per cent. of cases. The symptoms of passage of calculi through the common bile duct are similar to those already described in connection with the cystic duct. Obstructive jaundice is the marked differential sign between the two conditions. Many calculi pass through the natural channels without producing any symptoms. When there is complete obstruction the bile finds its way into the blood-vessels through the lymphatics. Cholelithiasis is now given as one of the causes of cirrhosis. The pressure of bile in the distended ducts, as well as irritation due to calculi in the extrahepatic and intrahepatic ducts, together with microbes and their products, are probably the principal agents. In all cases of biliary obstruction from calculi there is a danger of the introduction and growth of bacteria, leading to suppurative cholangitis and cholecystitis. The pain in this condition is usually not severe, and although an abscess may form it is not large and may contain hepatic calculi. The abscesses vary in size and number. The bacteria usually found are bacillus coli communis, streptococcus, staphylococcus aureus, and the diplococcus pneumoniæ.

The diagnosis of calculous abscesses of the liver is always difficult. Naunyn gives the following points in distinguishing the jaundice of chronic lithiasis from that due to other forms of obstruction: 1. The continuous or occasional presence of bile in the fæces. 2. Distinct remissions in the intensity of the jaundice. 3. Normal size or only slight enlargement of the liver. 4. Absence of distention of the gall bladder. 5. Presence of febrile disturbances. 6. Duration of jaundice for more than a year.

In acute yellow atrophy there is a decreased area of hepatic dulness. Fever is sometimes present in carcinoma of the liver. Calculi in the gall bladder and biliary canals are often the cause of carcinoma. Pernicious anæmia has followed biliary obstruction. Calculi sometimes pass through the ducts into the intestines and there increase in size and produce acute obstruction, which usually occurs at the ileo-cæcal valve. A calculus may ulcerate through the gall bladder from a fistula, which may extend upward through the diaphragm into the pleural cavity or lung, forming a broncho-biliary fistula. A case has been recorded of perforation into the left pleura, into the mediastinum, and then into the pericardium. Perforation may also take place into the stomach, pelvis of kidney, or portal vein. When the perforation is into the abdominal wall the fistula is usually tortuous.

The Dietetic Treatment of Diabetes.—Dr. Robert Saundby, of Birmingham, England, opened the discussion on this subject. When the diagnosis of diabetes mellitus has been established, he said, sometimes when only the presence of sugar in the urine has been detected, it is the very general practice to place the patient upon a so-called "diabetic diet." That is to say, he is furnished with a list of permitted and forbidden articles of food and drink arranged upon the principle that all carbohydrates are injurious, and he is told that he must keep to this diet until the sugar has disappeared from his urine. But carbohydrate food is not the only source of sugar. In severe diabetes glycosuria continues, although much reduced in amount, when the patient is placed on a flesh diet, and this is explained by the discovery that a carbohydrate molecule is formed in the process of converting albumin into urea, in the proportion of forty-five per cent. This fact, duly appreciated, must convince every one of the futility of persisting in withholding carbohydrates in the hope of removing the glycosuria. If it is conceded that the disputed data of physiologists do not afford a sound basis for our treatment of diabetes, but that we must look to clinical results before we say that a means is good or bad, then the old routine method is doomed. Instead of ordering a stereotyped diet in every case, we must try experimentally in each individual how much carbohydrate, or rather what combination of proteid, fat, and carbohydrate gives the best result. This was the method which the speaker would advocate, and it had been adopted solely upon the basis of clinical experience. The method, he said, does not involve a great sacrifice of time on the part of the doctor; in fact, all the most important observations can be made and a register kept by the patient himself. The only thing he cannot do is the analysis of the urine. The patient should once weekly get weighed, and collect and measure the whole of his urine for twenty-four hours; a specimen of the urine should be sent to the doctor, who should determine the total amount of sugar. Of these observations, the body weight is the most important, for if it continues to be stationary or tending upward, we have the best proof that the diet is properly regulated, even though the sugar shows a moderate increase. In order to determine the diet most suitable to each patient we must proceed experimentally, and this is better done by gradually increasing the amounts of saccharine and starchy food. Many patients suffer from polyuria and great thirst, and these symptoms can best be checked by strict diet for a limited time, combined, if necessary, with the administration of a grain or two of extract of opium every night. Further, the result of strict diet affords valuable information for prognosis, as it is only in the milder cases that the sugar disappears under its influence. The patient should, if possible, make one meal—for example, breakfast—of fat bacon or eggs and bacon, with which he may eat cabbage and starchless, not gluten, bread or biscuits. He is, of course, allowed other green vegetables, any animal food, tea or coffee with cream, and, if he desires it, two to three ounces of sugar-free alcohol, with mineral water. When after a week of this diet the sugar is found to have disappeared entirely, or almost entirely, six ounces of baked potatoes and one and one-half pints

of milk, containing between them the equivalent of about eleven hundred grains of sugar, may be added. If this causes no glycosuria, four and one-half ounces of dry toast, of which about eight hundred grains are starch, may be given, as also a bottle of light wine containing very little sugar, such as ordinary Bordeaux or Moselle, or in some cases a pint of bitter Burton ale. If such a diet causes no return of symptoms, the doctor may be satisfied and the patient is generally contented, and if sugar continues to be absent the quantity of toast or bread may be gradually increased to double the amount. Such cases are, however, exceptional. As a rule, the sugar, though diminished, persists. In such a case we may give first the milk and then the potatoes, and if there is no return of distressing symptoms we should not retrace our steps because there is some moderate increase of sugar, but watch the body weight. If that shows no loss, we may keep the patient on this diet for many weeks before venturing to make a trial of ordinary bread, and often the patient has to be content to do altogether without it. The speaker preferred to increase the potatoes, for he was of the belief that the starch of cereals is for some reason more productive of glycosuria than that of potatoes.

Dr. Sidney Coupland, of London, said that no one at the present day proscribes entirely the carbohydrates, but he agreed with Dr. Saundby that we are not liberal enough. Each case is a law unto itself in this respect, as a very slight restriction is necessary in some instances, while in others there is greater call for it. Diet alone, however, will not always effect all we could wish, for codeine was of very great value in one of the speaker's cases. We should be very cautious about restricting the diet too much, for such a course may favor the occurrence of coma.

Dr. Shingleton Smith, of Bristol, said we should be very clear as to the dietary indications in each case, and in young patients especially we must restrict the ingestion of carbohydrates. He cited one case in a middle-aged patient in whom there was always glycosuria after a small quantity of gluten bread had been eaten, even after the sugar had been absent for years. Certainly there should be more liberality in diet than is usually the case. Very often the patients do not follow out the orders of the physician, thereby materially reducing their length of life. Such patients often prefer a shorter life with liberal diet than a greatly restricted menu.

Dr. Ebenezer Duncan, of Glasgow, said that if diabetes is due to disease of the pancreas neither diet nor anything else will have much effect on the symptoms. When, however, the diabetes is of neurotic origin, then more can be effected. He thought the diet should be quite strict as long as the patient could stand it.

Dr. Tyson, of Philadelphia, said that his method was practically the same as that of Dr. Saundby, that is, he varied the diet according to the condition of the patient. We must distinguish between the mild cases in which the excretion of sugar can be prevented by careful diet and the severe cases in which no treatment will arrest it. He felt sure that many, if left alone, would outlive their diabetes. He was in the habit of placing diabetic patients for two days each month on proteid diet, but if the sugar exceeds two per cent. the diet must be very strict. The polyuria of diabetes is an effort of the system to rid the blood of sugar. A proteid diet produces diacetic acid in the urine, and may cause the coma. It is practically impossible, however, to keep patients on purely albuminous diet, and this is fortunate, as it probably often saves the patient's life.

Dr. A. Jacobi, of New York, described the course he usually pursued. He regulated the diet according to the age: young patients cannot take carbohydrates with impunity, while old patients may thrive on them. Children will live longer with a strict proteid diet, but will probably never get well. The speaker had never seen diabetic patients get worse with milk but nearly always they improved, and it was his custom to give it in some form, such as sweet milk, buttermilk, or skim-milk. A rigid milk diet, however, cannot be recommended. Old persons will do better on a mixed diet than on a strict diet.

Dr. Wright, of Ottawa, drew a sharp distinction between glycosuria and diabetes. The former occurs chiefly in elderly people and these patients may follow a very liberal diet rule. He spoke of a type of cases which he had encountered in apparently healthy young men whom he examined for life insurance. In these cases sugar appeared in the urine without polyuria or any other symptoms of diabetes. One patient, who gave a history of hard work and worry, had been under observation for the past fifteen years. The question was whether treatment was necessary in cases in which only this symptom was present, and also whether such a person was a suitable risk for life insurance.

Dr. Mackenzie thought that the reaction against the blind routine would undoubtedly do good. In this disease there is greater hope for good results than we formerly thought. We should be guided in our treatment by the patient's condition, and not exclusively by the amount of sugar in the urine.

Dr. Saundby, in closing the discussion, said that at the commencement of his adddress he had expressed the hope that some of those present would be able to echo his opinions, and he was more than pleased that so many held the same views of treatment as he did. Even in the case of children a little carbohydrate, especially potato, four to six ounces, may be given without bad results. Of course in children the prognosis is very bad, but their life should be made as agreeable as possible. Giving about a quart of milk daily he thought was very beneficial. The percentage of sugar in the urine is misleading, but an estimation of the total amount passed in twenty-four hours is a good index.

With regard to Dr. Wright's question he thought that such cases of temporary glycosuria often develop into true cases of diabetes; this at least was the opinion of some authorities.

TWELFTH INTERNATIONAL MEDICAL CONGRESS.

Held in Moscow, August 19, 20, 21, 22, 23, 24, 25, and 26, 1897.

[illegible]

SECTION ON INTERNAL MEDICINE.

[illegible]

First Day—Friday, August 20th.

The session opened with Dr. Pavlinov, of Moscow, in the chair. The following were appointed presidents of the section for the day: Drs. Senator and Gerhardt, of Berlin; Brault, of Paris; Crocq, of Brussels; Grunmach, of Berlin; Ebstein, of Göttingen; Le Gendre, of Paris; Laache, of Christiania; and Ughetti, of Catania.

Clinical Classification of Nephritis.—Dr. Brault, of Paris, read a paper with this title. The attempts at classification of nephritis, he said, have been numerous. The first were due to the labors of Bright and of Rayer, but for anything like a satisfactory classification we must come down to our own day, when the pathology of the kidney, like that of other organs, has been completely changed by the studies and discoveries in general pathological histology. The name

of Virchow marks the beginning of this last period. The speaker did not wish to say that only good came from this revolution, for there is even some question as to whether the pathology of the kidney has really benefited from the application of these ideas. It was in order, the speaker said, to inquire of what use is a clinical classification, and whether it is more rational and practical than are others. The most used of the histological classifications divided nephritis into parenchymatous (Virchow, 1852) and interstitial (Beer, 1859). The discovery of the connective tissue in the kidney and its importance in disease led Traube to reject completely the parenchymatous nephritis of Virchow. Kelsch, following in his footsteps, declared that inflammation could develop only in connective tissue. The improvements in the microscope soon cleared up the question, and almost all microscopists accepted as exact this simple division of parenchymatous and interstitial nephritis. Nevertheless certain authors still refused to admit the existence of a parenchymatous nephritis, maintaining that interstitial nephritis alone was capable of causing atrophy of the organ. Carrying this idea to extremes, forgetting that the kidney is formed after the type of a gland, they affirmed that its epithelium could degenerate but could not become inflamed; that, finally, all the processes of nephritis being essentially interstitial, acute inflammation of the kidney is an acute interstitial nephritis. They showed as an example of this the nephritis of scarlet fever. So we see at this period, from a histological point of view, everything was confusion; as for pathological physiology and etiology, they were of so little importance that they are scarcely mentioned. In 1875 Bartholow described an acute and chronic parenchymatous nephritis, and an interstitial nephritis or induration of the cellular tissue of the kidneys (under which he comprehended simple atrophy, cirrhosis, sclerosis, and granular atrophy). At the same time Lancereaux substituted for interstitial nephritis the term primary diffuse nephritis, and for parenchymatous nephritis epithelial nephritis. Shortly after this Charcot called attention to the identity of parenchymatous nephritis and large white kidney, and of interstitial nephritis and small contracted kidney.

Following this came the studies of Klebs and Bamberger, who declared the division into large white kidney and small contracted kidney wrong, because they found microscopically in each form lesions affecting both the parenchyma and connective tissue. Weigert (1879), Cohnheim (1880), and Wagner (1882) said that the epithelial lesions always precede the alterations in the connective tissue, and they declared (especially Weigert) that if the lesions varied in different cases it was only a difference of degree. Cornil and Ranvier had already expressed this opinion in 1876.

The most natural classification, Dr. Brault said, would be an etiological one. In 1884 the speaker, working with Cornil, wrote a thesis on diffuse and systemic nephritis, and in 1893 he discussed again the division of nephritis. At that time he contended that there was no longer a question of the unity or duality of Bright's disease. If the diseased kidneys vary in their size, their consistence, their form, their coloration, their granulations, etc., all these elements depend on whether the process is rapid or slow, violent or slight. Infectious diseases irritate, inflame, destroy *en masse;* chronic diseases, the dyscrasias, and prolonged intoxications destroy the organ by a series of local inflammations or cause it to degenerate little by little.

A clinical classification is possible only as regards duration: as transitory, acute, subacute (or prolonged), and chronic nephritis, this last comprehending only the latent varieties, namely, those with serious lesions but appearing healthy. A symptomatic classification such as Weigert and Wagner have proposed, as nephritis with or without œdema, nephritis with or without hemorrhage, is not practicable, for allowing such a nomenclature the question of classification still remains.

In all cases of nephritis in which the duration is prolonged we see constantly hypertrophy of the heart. It is therefore useless in the understanding of a nephritis to have recourse to the old divisions of parenchymatous and interstitial, for, if we have (1) the cause of the nephritis and (2) the date of its appearance, we possess sufficient data to explain what has already taken place, to foresee the future course, and to deduce the corresponding anatomical form.

Chronic Parenchymatous and Interstitial Nephritis.—Dr. Crocq, of Brussels, then presented a communication with this title. He said that albuminuria was due to desquamation of the renal epithelium, and we could not have even a so-called physiological albuminuria, a transitory condition, without such cause, although the cause of the albuminuria might be of short duration and so escape our notice. For example, we may have a hyperæmia which can be active as well as passive, as in inflammation of the kidneys due to valvular disease of the heart. Moreover, usually a parenchymatous inflammation of the kidneys is the cause of the excretion of albumin, which almost invariably points to chronic Bright's. Interstitial nephritis is quite another thing. In this we have an inflammation of the connective tissue which binds together the parenchymatous elements. If the epithelium is not affected there is no albumin in the urine, but if the inflammation extends to the epithelial elements it at once appears. Clinically therefore the author would distinguish two kinds of chronic nephritis—one with, the other without, albuminuria. These are identical with the anatomical forms distinguished as parenchymatous and interstitial.

The Pathogenesis of Chronic Nephritis.—Dr. Senator, of Berlin, read a communication on this subject. When this affection is not due to the persistence and further development of frank acute nephritis, he said, it is the result of latent inflammations of the kidney long continued. Any, even the smallest amount of albuminuria is a sign of a pathological process in the kidney. Albumin can leak through the filter that was meant by nature to retain it only when there is an organic affection of the organ. Chronic nephritis is often due to this latent process that so easily escapes notice.

In discussing this paper, Dr. Gerhardt, of Berlin, said that he did not think slight albuminuria was always due to organic lesions of the kidney, but often to functional derangement. In some people, in fact, it seemed as though there was such a thing as physiological albuminuria.

The Employment of Bleeding in the Treatment of Uræmia.—Dr. Laache, of Christiania, read a paper with this title, in which he recommended bleeding in certain forms of kidney disease, accompanied by uræmic symptoms, in which the blood pressure is increased.

Etiology of Chronic Nephritis.—Dr. Pavlino, of Moscow, said that, contrary to the opinion of Charcot, Eichhorst, and Liebermeister, his observations proved the existence of a chronic scarlatinal nephritis, parenchymatous and interstitial, and in this he was supported by many authorities. In accordance with the accepted doctrine concerning inflammation and as one would naturally deduce from observation of the clinical evolution of nephritis, we find at the autopsy a chronic epithelial nephritis when the duration has been short, and an interstitial nephritis when the course of the disease has been tedious. It is necessary

to remember that the duration of a chronic nephritis is generally much longer than is set down in the text-books, the speaker said, and according to his own observations the duration of the parenchymatous form of chronic nephritis might be from five years, and that of the interstitial form from twelve to seventeen years. In his experience chronic nephritis develops in subjects from twenty-one to twenty-four years old, and when we find it at this age we must bear in mind the possibility of its origin from scarlet fever. Admitting scarlet fever as one of the causes of chronic nephritis, we can explain in certain cases its etiology and so diminish the number of cases occurring without apparent cause.

The Pathogenesis of Obesity.—Dr. P. Le Gendre, of Paris, sent a paper with this title, which was read by Dr. Chavrin. He spoke first of the etiology of the affection. Heredity, either similar or under the appearance of arthritism, is active among the predisposing causes, as is also sex, women being more liable to suffer than men, in the proportion of two to one. The exciting causes are unsuitable diet, especially the consumption of starchy and saccharine foods, dyspepsia, the abuse of alcohol and perhaps the ingestion of any fluids in too large quantity, a sedentary life, and (as was observed after the siege of Paris) a sudden return to comfort after long privation. The speaker then discussed metabolism as it related to the disposition of ingested fat or the formation of fat in the organism from other substances, such as sugar or albumin. The factors which clinical experience has shown us to be active in the production of obesity may be grouped under two heads. The first of these moments are those which offer a resistance to the destruction of fat in the economy by diminishing the supply of oxygen needed for its combustion. Among these are anæmia and chlorosis, large hemorrhages, and a sedentary life. Dyspepsia also acts by lessening the amount of bile and pancreatic juice, and so preventing the splitting up of the fats in the intestine; the fat is thus absorbed in the form of an emulsion, which is much more difficult of oxidation. In the second group we find those causes which increase the production of fat in the economy, either through an increased ingestion of fatty food or by favoring the conversion into fat of sugar. Whether the ingestion of large quantities of water favors obesity has long been a disputed point, but Robin's experiments have shown that water favors that form of obesity which is the result of increased assimilation, but exerts no effect when the increase of fat is due to diminished disassimilation. The action of alcohol is exerted in several ways, the chief of which are by causing dyspepsia and by retarding nutrition. The influence of the nervous system in the causation of obesity is very evident in certain cases, but its mechanism is not very clear.

The Diagnosis of Internal Diseases by Means of the Roentgen Rays.—Dr. Grunmach, of Berlin, exhibited several skiagraphs showing enlargements of the heart, aneurisms, and tumors of various kinds. In all the diagnosis had been arrived at by means of the *x*-rays.

The following papers were read by title: "The Pathogenesis of Vesical Calculus," by Dr. Ebstein, of Göttingen; "The Pathogenesis and Treatment of Gout," and "The Therapeutic Value of Prepared Foods," by Dr. B. Laquer, of Wiesbaden; "Febrile Uræmia," by Dr. Ughetti of Catania; and "The Clinical Classification of Nephritis," by Dr. von Leyden, of Berlin.

Second Day—Saturday, August 21st.

The following were appointed honorary presidents for the day: Drs. von Ziemssen, of Munich; Crocq, of Brussels; Widal, of Paris; Marchiafava, of Rome; Daland, of Philadelphia; and Thayer, of Baltimore.

The High-Altitude Treatment of Tuberculosis.—Dr. von Ziemssen read the first paper of the day. Looking back over the history of tuberculosis, he said, we see a motley conglomeration of methods of treatment, for during the present century almost every year has brought with it a new remedy. All these have now been discarded and but two agents remain to be considered, namely, tuberculin and climate. In regard to the first, the "specific" treatment, there is little to say. Koch's old tuberculin has been forgotten, the value of the new has not yet been proven, and most people already doubt its efficacy. In speaking of tuberculosis, he said, he meant particularly pulmonary tuberculosis; other forms, such as lupus, have without doubt been cured, but for the pulmonary form, the most frequent and therefore the most serious, nothing really has been done. The complexity of the lesions make a cure by means of a specific seemingly impossible. Other forms have their specifics, for tuberculin will often cure lupus, and iodoform will cure tuberculosis of the joints, but as yet we have no specific for tuberculosis of the lungs. There remains therefore only the climatic treatment. As far back as we can see in the history of medicine fresh air has been one of the requirements in the treatment of tuberculosis, but it is only of late that the advantage of high altitudes, at least for many cases, has been clearly demonstrated. That tuberculous patients can get a quantity of fresh, pure air in these regions is evident to any one visiting the places. On the mountains in the centre of Europe, mountains covered with snow during the entire winter, one can see patients sitting in the sun drinking their morning coffee, with snow all around them, yet the sunbeams are so warm and pleasant that they are perfectly comfortable. But the fresh air that surrounds them is not all; the altitude brings about an excitation of the blood-making organs that increases the corpuscular elements in the blood. Even in health this reaction takes place, but not so markedly as in diseased states. There are contraindications to high altitudes which prevent us from sending all patients there. A tuberculous patient with fever should never be sent to a height, for he will certainly become worse and the fever will be increased. Almost always patients without fever do well, though they sometmes find it difficult at first to acclimatize themselves. If the fever is due wholly to the presence of bronchitis or pleurisy, it does not act as a contraindication.

The best results are obtained when the patient is sent to a place near his own home, for a long journey is always depressing, and the comfort of seeing friends, especially to a sick man, is very great. The stage of the disease must be taken into account in deciding this matter. If the case is much advanced, the patient should be kept as near home as possible.

The speaker took up the subject of sanatorium treatment for the poor. He feared the number of the rich is too few to build sanatoria for all the world, but that should not paralyze all effort, for every case cured and every case isolated are steps toward the conquest of the disease.

Dr. Senator said that his personal experience with tuberculin had not been very extensive. He had tried it carefully in a dozen cases, but without good results. In a few it seemed to moderate somewhat the fever, but in the others it acted as poison. He was convinced that the only treatment of value was the climatic, and he believed high altitudes were often of especial value. He did not believe that good was done by increasing the number of red corpuscles because he had seen more than one case in which elevation had no visible influence on the corpuscular ele-

ments of the blood and yet the patient improved. He agreed with the reader of the paper that the principal contraindication to high altitudes was fever, for there is great danger in such cases of hæmoptysis. Nevertheless some cases of hæmoptysis without fever (when the hemorrhages are slight) do well in these regions. He regarded altitude as a factor second only in importance to fresh air. Sunlight is also of great value and the sun's rays themselves exert a particular influence. Pharyngeal and laryngeal cases do not improve, and in fact always become worse, so that Dr. Senator regarded such complications as a positive contraindication to the high-altitude treatment of pulmonary tuberculosis.

Dr. von Leyden said that in his hands the specific treatment had failed, and he did not believe there could be any sure success with tuberculin. The specific may come but we cannot wait for it. We must not look to the future; we are living in the present and must treat in the present. So far the only treatment that has given any positive success, he said, is the climatic. His best results had been obtained in the mountains, but the place and its climate must be selected to suit the individual patient. A patient should not be sent far from home, for the nearer he is to friends the more comfortable and contented he will be and the better, as a rule, will be the results.

Dr. Körnig, of St. Petersburg, said that he had found an increase in the red blood cells in patients who had gone to high altitudes, and he was inclined to attribute to this increase a large part of the benefit derived from a stay in these mountain sanatoria.

Dr. Dehio, of Dorpat, said that observations of the sanatoria in Russia, for instance Hallila in Finland and Lindheim in Livonia, have shown that the climatic peculiarities of the Russian winters have an effect on tuberculosis very similar to that of high altitudes.

Dr. Jarvein, of St. Petersburg, reported the results of a trial of tuberculin in the clinic of Professor Janowsky in the military academy at St. Petersburg. It was tried in eight cases, five of which were very mild and in the first stage. They began with one-five-hundredth of a gram and increased daily to one milligram. At first the patients showed no reaction to the drug, but when the dose of one-fiftieth to one-twenty-fifth of a milligram was reached the temperature began to rise to from 37.8° to 38.5° (100° to 101.3° F.) and after two weeks three of the patients began to have hemorrhages. From this time (after two weeks), five patients began to grow steadily worse, and by the end of two months it became absolutely necessary to stop the use of the tuberculin. The three other cases were complicated with fever. The reaction occurred sooner and the rise of temperature was greater. The last case was that of a physician with tuberculosis of the pharynx. In the beginning he reacted feebly, so that the dose was gradually increased to three milligrams. Then appeared some fresh miliary tubercles, the temperature rose quickly to 38° to 39° to 40° (100.2°–104° F.), and in three months he died with all the symptoms of general miliary tuberculosis. After listening to the greatest authorities in Europe on the treatment of phthisis in sanatoria, the speaker thought that there can be but little doubt left in the minds of those present that this is at present the only mode of treatment; and as to the question of sanatoria for the poor he was sure that there were in Moscow and all over the world many rich men who would be willing to give generously for such a purpose if it was properly presented to them on the authority of the international medical congress that such was the only method of treatment.

The Climatic Treatment of Tuberculosis.—Dr. Vivant, of Monte Carlo, continued the discussion by the reading of a carefully prepared paper. The discovery of the tubercle bacillus, he said, has taken nothing from the importance of the climatic treatment of tuberculosis, in particular that of pulmonary tuberculosis, the most difficult to handle. The bacillus of tuberculosis resists alike high and low temperatures, so that there is no climate with absolute immunity. The climates most justly regarded as of value in the treatment of this disease offer a certain number of features in common, viz.: pure air—that is, oxygen in unlimited quantity; and relative dryness—that is, absence of fogs, of air charged with moisture, to interrupt the light, heat, and chemical action of the sun's rays. We know the importance of light for animal and vegetable cells, and we recognize that solar light rapidly kills bacteria. Air to be pure ought not to contain dust, especially pathogenic dust; it would be therefore useless to choose a windy place. Pathogenic dust is found especially in the midst of crowded places, and the danger of mixed infection arises; hence a person with pulmonary tuberculosis should especially avoid large cities. The temperature of the air as regards its influence upon the respiratory tract is of little importance; yet there is an advantage on the side of heat, inasmuch as cold climates expose the human organism, especially when feeble, to a variety of serious circulatory troubles included under the general term "colds." The stations on the Riviera, the plains of the deserts, the high-altitude resorts, all offer in different degrees all these active elements in climatic treatment; but the plains and the deserts offer no shelter from the heavy winds, the principal agents of colds and principal disseminators of dust. The Mediterranean resorts offer the advantage over the mountains that, with a superior solar radiation, they are less cold, permitting the patient to live in the open air continually in light, thin clothes, giving the air and light the best chance to exert their favorable therapeutic action.

The Foundation of a Rational Treatment of Phthisis.—Dr. Drozda, of Vienna, read this paper. The subject, he said, resolves itself into several parts: 1. It is necessary to destroy the accumulated toxins following the invasion of tubercle bacilli, streptococci, and staphylococci. 2. Since there can be no question of an immediate rapid excretion of micro-organisms, we must seek to diminish as much as possible the virulence of the bacteria already present. 3. We must endeavor to strengthen the vital energy of the affected organs. 4. We must take care to allow the free elimination of infiltrated masses which have softened. 5. The micro-organisms which have already passed into the lymphatic system must be rendered innocuous.

The Malarial Parasite.—Dr. Gautier, of Moscow, read a paper giving certain details in the structure of the parasites of Laveran during their evolution. Following in the path marked out by Golgi and Romanofsky, he said, we can study the details of the structure of the parasite which are not to be distinguished by other methods of staining. In cases of intermittent fever studied in the Caucasus, the author had observed in the blood three species of hæmatozoa. Each of these had a characteristic life cycle, by which it could be distinguished from the other two. One of these corresponded to the parasite of tertian fever, and another to that of quartan, as Golgi has described them. The third was probably identical with the parasite observed in Italy by Marchiafava in cases of tertian autumnal fever. According to the author's observations, the life cycle of the last parasite was two days. The fever produced by it might be classed among the irregular fevers, having sometimes a tertian, sometimes a quotidian type. These three species of hæmatozoa, different one from the other, undergo during their evolution a series of modifications common

to all. The most interesting of these processes is the development of the nucleus, the retrograde evolution of this nucleus, its disappearance, the reappearance in the body of the parasite of new rudimentary nuclei, which become the centres for the formation of young parasites, after which division of the parasite occurs and a new generation arises.

This paper was accompanied by colored pictures, showing the different parasites in all their stages.

Dr. Thayer, of Baltimore, said that he had been much impressed by the extremely interesting observations of Dr. Gautier, with some of which the speaker was already familiar through Gautier's excellent book on the parasite of Laveran. In the observation of over two thousand cases of malarial fever occurring in Baltimore during a period extending over the last seven years, in sixteen hundred and thirteen of which cases the parasites were carefully studied and the types differentiated, Dr. Thayer had been led to distinguish three varieties of the malarial parasite—the tertian, the quartan, the æstivo-autumnal or, as Welch has happily termed it, the hæmatozoon falciparum. Each of these three varieties of parasites is associated with a characteristic type of fever. The speaker said that he and his fellow-workers had not been able to separate the æstivo-autumnal type into two distinct varieties, as have some of the Roman school and Mannaberg, and they believed that the æstivo-autumnal parasite is a single organism, the length of whose cycle of development may vary materially under different circumstances, lasting more commonly about forty-eight hours, but not infrequently being considerably shorter. Between these three varieties of parasites they had never observed any transitional stages, nor were there any facts in their experiences which would suggest that such transitional forms exist. Combined affections may occur, but they are rare; they were present in a little more than two per cent. of the cases studied by the speaker. He did not agree with those observers who consider that the malarial parasite is a single though polymorphous organism, for his experience inclined him to the view that these three forms represent separate varieties or species of organisms. While agreeing entirely with Dr. Gautier as to the types of parasites, he had to confess that he had not succeeded in obtaining the same beautiful results in his stained specimens. It is not impossible that this might be due, he thought, to the fact, as pointed out by Dr. Gautier, that this result is to be obtained with certainty only when especial varieties of methylene blue are used.

On the Increase of Eosinophilic Cells in Trichinosis.—Dr. Thayer, of Baltimore, then read a paper containing a *résumé* of the studies of Dr. Brown on two cases of trichinosis. Dr. Brown's paper, he said, would appear in the *Journal of Experimental Medicine*.

Case I.—R. T——, aged twenty-eight. Previous history negative. The subjective and objective symptoms all pointed to trichinosis, and besides a small piece of muscle cut from the biceps showed living trichinæ. On the day of admission, March 8th, examination of blood showed red blood corpuscles, 4,232,000; leucocytes, 16,500. Differential count of leucocytes: Small mononuclear leucocytes, 5 per cent.; large mononuclear and transitional forms, 7 per cent.; polymorphonuclear neutrophiles, 50 per cent.; eosinophiles, 38 per cent. The total number of leucocytes ranged between 13,000 and 35,000. The percentage of eosinophiles ranged between 8 and 68. The small and large mononuclear elements remained throughout at a percentage slightly higher than one would have expected with the degree of leucocytosis existing, while the number of polymorphonuclear neutrophiles was in directly inverse proportion to that of the eosinophiles. Thus, on the 23d of April, with a leucocytosis of 17,000, the differential count of the leucocytes was: Small mononuclear leucocytes, 19.5 per cent.; large mononuclear, 5.2 per cent.; polymorphonuclear neutrophiles, 6.6 per cent.; eosinophiles, 68.2 per cent.

Case II. F. B——, twenty-nine years old, showed few if any of the classical symptoms of trichinosis. Such a condition was not thought of till after the blood examination. This showed red corpuscles, 5,000,000; colorless corpuscles, 13,000. Differential count: Small mononuclear forms, 11 per cent.; large mononuclear, 5 per cent.; polymorphonuclear neutrophiles, 37 per cent.; eosinophiles, 44 per cent. Dr. Brown, remembering the case of trichinosis with the high percentage of eosinophiles, examined a piece of the muscle from the calf, and found living trichinæ. In this case, as in the former, the same inverse proportion existed between the number of neutrophilic and the eosinophilic leucocytes.

Conclusions: 1. In two instances of trichinosis the circulating blood has been found to contain a larger percentage of eosinophilic cells than has ever previously been demonstrated. 2. This increase in eosinophiles, occurring in connection with a moderate or well-marked leucocytosis, always occurs at the expense of the polymorphonuclear neutrophiles, which are correspondingly decreased in number, the small and large mononuclear and transitional forms being present in normal proportions in a percentage slightly below normal, not far from what one would expect with a leucocytosis of the existing degree. 3. Whether these changes in the blood are characteristic of trichinosis, or are also to be found in extensive myositis from other causes, remains to be shown. 4. The remarkable inverse proportion between the eosinophiles and the neutrophiles in these instances, as well as the changes observed by Brown in the histological study of the muscle, forms suggestive evidence in favor of the view that the increase in eosinophiles in these cases occurred by a direct transition from the polymorphonuclear neutrophilic elements.

Dr. Daland, of Philadelphia, said that without doubt this was something original in the diagnosis of trichinosis, and the fact of an increase of eosinophiles at the expense of the polymorphonuclear neutrophiles was intensely interesting.

Dr. Ewald, of Berlin, inquired whether Dr. Thayer had found any connection between the toxins created by the trichinæ and the increase in eosinophiles.

Dr. Thayer said that he believed more eosinophiles were found in the muscles than in the circulating blood, so much so that it seemed to suggest that the polynuclear cells after leaving the vessels became eosinophiles.

The following papers were read by title: "The Displacement of the Heart in Left-sided Pleural Effusions" and "The Physio-Pathological Signification of 'Ictus Cordis,'" by Dr. Queirolo, of Pisa; "Are the Different Forms of Malaria Caused by One or Several Parasites?" by Dr. Celli, of Rome; and another with the same title by Dr. Sakharov, of Tiflis; "The Unity of Paludism," by Dr. Coronado, of Havana; "The Parasite of Pernicious Fever and its Clinical Forms," by Dr. Marchiafava, of Rome; "Some Remarks on Diseases of Malarial Type," by Dr. Da Rocha, of Coimbra: "Note on the History of Epidemic Paludism," by Dr. Mejia, of Mexico; "Tuberculous Splenomegaly," by Dr. Widal, of Paris; and "The Rôle of Heredity in the Etiology of Certain Diseases," by Dr. Kabanov, of Moscow; "The Curative Action of Nitrate of Silver and of Ergotin in Pulmonary Tuberculosis," and "The Efficacy of Revulsion in the Treatment of Pulmonary Tuberculosis," by Dr. Crocq, of Brussels.

Correspondence.

OUR LONDON LETTER.

[From our Special Correspondent.]

TO MOSCOW—TO INDIA—THE MILITARY MEDICAL SERVICES—COMBATANTS' PREJUDICES—A JUSTER ABBREVIATION—THE NETLEY SCHOOL PRIZES—GENERAL BUTLER'S ADDRESS—ADVERTISING IN LAY JOURNALS—A GREATER SCANDAL AT MERCER'S HOSPITAL—STARVING PATIENTS—CHOLERA ALARMS—DANGEROUS STATE OF THE RIVER BRENT—STATISTICS OF HOSPITALS—ACCIDENT TO OUT-PATIENTS—PAUPER NURSING ABOLISHED—EXPLOSIVE HAIR WASHES—CONGRESSES—DEATHS OF DRS. NELSON AND DU PASQUIER.

[London, August 21, 1897.]

THE International Medical Congress will have a fair representation from these islands, as in spite of other attractions and the long journey a number of our brethren will undertake the trip to Moscow.

In consequence of the Indian troubles a number of army medical officers have been detailed for duty on the northwestern frontier. Nine surgeon-majors and surgeon-captains leave London to day to catch the P. and O. steamer at Brindisi for Bombay. Of course all leave is stopped and there must be pressure on the department.

Though the Indian service will not want men, the prospects for the army are not pleasant, in the face of the failure of the last examination to attract competitors. There have been serious rumors as to Lord Wolseley's health, and though these were contradicted it is again affirmed that he will have to resign. If Sir R. Buller succeeds as commander-in-chief it will be only an exchange of log for stork, so far as the medical staff is concerned. If he should be passed by, Lord Roberts would have the post, and he is held to be a just man with an open mind, and as such would be certain to lend an ear to the medical service and then the grievances must be redressed.

The offensive conduct of military officers is so constant a source of annoyance that it is pleasant to chronicle an occasional appreciative utterance, such as that of Major-General Sir Wm. Butler, who distributed the prizes at the close of the last session of the Netley School. In his address he spoke of the profession as in one sense the highest, and told the medical officers they represented the humanizing influence, the openness or freedom of mind and independent thought, which are of the greatest value in the profession of arms, where the chief mental danger is a too restricted idea of the horizon of life. In illustration of his meaning he referred to the two brave and honorable surgeons at St. Helena, who, undeterred by official censure, fixed in the immutable traditions of honor, truth, and justice, protested against the mean and stupid persecution of the dying Napoleon. "It is true," he said, "they lost everything, but they won more than the world's applause, for in a measure they redeemed the national honor when the action of their official superiors had compromised it." The general also referred to Baron Larrey, whom Napoleon pronounced the "most virtuous man I have ever known:" and in conclusion alluded to his own debt for the care and sympathy and skill bestowed on him at Netley five and twenty years ago, and to which under Providence he ascribed his survival to address those entering on their honorable career, in which he wished them prosperity and happiness. Among other notabilities present on this occasion was Sir Joseph Fayrer, who also made a short speech, in which he pointed out to the Indian officers the grand career before them in a service which had produced most brilliant men and which he believed would be even better in the future than in the past.

What is medical advertising? The question seems always with us. An anonymous correspondent of the *Medical Press* attacked Dr. Brunton for permitting a review of a work of his to appear in the *Glasgow Herald*. Dr. Brunton replied regretting he had not specially instructed his publishers not to send the book to lay journals. The *Herald* is indignant with the *Press* and the doctor, and says: "Medical etiquette is surely the strangest wild fowl in the whole menagerie of conventions"—a view it would be no easy task to refute. The *Herald* says it will not be deterred by the tyranny of medical journals from giving its readers the best expert opinion of whatever publications it chooses, and there are plenty of ways of obtaining books besides the gifts of publishers. The *Press* retorts that if every lay journal were to give a lengthy review of medical works as they appeared, the nation would soon be a collection of feeble-minded neurotics through perusing the lay papers. This is rather strong, certainly, but is it true in any degree? Reviews could never occupy so much space as quack advertisements now do. These lay papers (by the way, is not the word lay getting very much abused, its meaning indefinitely extended?) will not be dictated to and the medical ones are open to the retort that they want to drive advertisements into their own columns. It is not many years since the leading medical journals advertised unblushingly their contents in the "lay" papers, and the contents were scarcely ever suitable for family reading. When this became too blatant, the advertisements were restricted to the *Times*, and for years that paper was held to be a permissible medium for advertising medical books. Now the purists include it in their objections. Assuredly the *Times* will not be intimidated by the loss of a few advertisements from commenting upon medical as well as sanitary questions, and it is somtimes difficult to draw the line. The "lay" papers will do whatever they think pleases the great public, whatever the professional journals may say, and there is not much danger of medical books becoming popular. Other forms of advertising are certainly more offensive and within each man's own control, while publishers have a finger in this.

The Mercer's Hospital scandal has developed into something that looks like a crime. I am credibly informed that the house committee discharged all the patients under Mr. O'Grady and in order to compel them to leave they were refused all food for twenty-four hours. When Mr. O'Grady heard of this he bought food for them and brought it in. The plan of starving the patients has been defended by the registrar in a letter to the newspapers. How long is such a committee to be suffered to afflict the sick? If one had died, a verdict of manslaughter might have been the consequence. Irish lawyers are proverbially acute, and it will be strange if none of them can bring the members of this committee to book for endangering the lives of patients intrusted to their care. Every one of those who were guilty of this act should be placed in the criminal dock.

[London, August 28, 1897.]

WE have had what the newspapers call a "cholera scare," but it must be admitted that London has taken the sensation with abundant *sang froid*, and with good reason, too, considering the circumstances and our state of sanitary preparedness. The case reported certainly exhibited some of the symptoms of cholera and the patient died in a state of collapse after seventeen hours' illness. A working girl at the east end of London went to bed well after a supper of bread, butter, cheese, tomatoes, and fried potatoes. She was attacked with vomiting and diarrhœa in the night. A

doctor was called in the morning, who found her in a collapsed condition with a temperature of 94° F. At the post-mortem ecchymoses were found on the brain, the lungs were collapsed, the blood was tarry, and the intestines contained a greenish fluid. Bacteriological examination was negative. The jury at the inquest returned a verdict of English cholera, and the county council on the strength of the bacteriological reports stated it could not be the Asiatic scourge. There was absolutely no source of infection to be incriminated and the disease did not spread. In the absence of cholera in Europe "scare" was uncalled for and in fact took place only among the journalists in search of sensation. Cases of so-called English cholera occur during most summers, and it must be admitted that some of them present symptoms that are held to be the appanage of the Asiatic variety, and it may be impossible from symptoms alone to differentiate all the varieties of purging and vomiting ending fatally. In this case it is possible some ptomain poisoning may have been at the bottom of the mischief.

While cholera, whether Asiatic or English, excites public fears, the holocaust of infants from summer diarrhœa goes on from year to year with little notice. The mortality of London and all the large towns has lately been rising, the chief cause being this summer ailment of infants. The number of deaths reported in London from diarrhœa has been 270, 459, 575, and 651 in the four weeks up to the 14th instant. Of this mortality over ninety per cent. is due to the deaths of children under five years of age. What must have been the extent to which diarrhœa in some degree affected patients who recovered? The advent of colder weather is making itself felt, but it is difficult to reconcile one's self to the annual sacrifice of these young lives. While much is doubtless due to waves of heat, it seems impossible to admit that we are helpless. The powerful effect of diet and suitable regimen ought to enable us to save many of these infantile victims. But so long as the public fancies that every disturbance of the alimentary canal is caused either by eating fruit or by "biliousness," the great majority will go on feeding their progeny in an improper way and calling in the doctor only when too late. It must be admitted, however, that infantile diarrhœa offers a broad field for further investigation into its etiology, treatment, and prevention.

The foul state of the River Brent has at length roused the local government board and the Middlesex County council has been instructed to cleanse it forthwith. None too soon, for the stream has become in places an open stagnant sewer and the pleasant villas on its banks are almost uninhabitable on account of the horrible stenches arising from the sewage. It is averred that all the local authorities have discharged only clear effluents, but ocular and olfactory evidence proves that some of them have only imperfectly treated their sewage, if indeed it has not been allowed to escape without any treatment at all. Another cause for the dangerous and nauseating state of the stream seems to be that a canal company impounds the water under an old act, to such an extent as to arrest the flow. Now that the government board has spoken, men are at work in an effort toward improvement, which can only be temporary. It must follow up its action by some legislative measure so as to restore the once delightful valley to a sanitary condition.

Burdett's "Hospitals and Charities" for 1897 opens with a chapter on the Queen's commemoration. Her Majesty is patroness of more than sixty hospitals and dispensaries and of some ninety other charities. As an example of the progress of charitable institutions it may be stated that in the hospitals patronized by the Queen there were, in 1837, 2,500 beds, which had increased in 1895 to 3,331. These were used by about 28,000 patients in 1837 and the past year by 36,514. The book gives statistical and other information respecting all sorts of institutions for the relief of the sick and suffering, and describes the various systems of relief which are adopted in the various parts of the English-speaking world. These institutions expend collectively a sum of from twenty to twenty-five millions sterling.

A singular accident occurred at St. Bartholomew's hospital on Saturday. A number of out-patients were waiting to be admitted when the portico under which they were standing collapsed. Most of them made good their escape but several who were near the door were caught by the falling débris, and so injured that they had to be taken into the hospital.

The "order" of the local government board forbidding the employment of paupers in nursing is giving much satisfaction to poor-law reformers, who have long urged that the evil should be abolished. A further "order" requires a superintendent nurse to be appointed in any workhouse employing three or more nurses under the medical officers' control. The *Medical Press*, always well informed on these matters, urges the Irish board to follow the example, stating, however, that this authority is but the servant of the guardians, and although possessed of good intentions takes years to consider them, while the English board, being master and controller of the guardians, can act without hesitation and so effect a reform in a few months.

The county council has prosecuted a number of hairdressers for keeping petroleum without a license. Considering that a lady was lately burned to death in a hairdresser's establishment through a petroleum wash taking fire, it seems incredible that any one should go on employing such a material to cleanse the hair. One would suppose too that no one would run the risk of such a painful death as that which lately shocked the community. The council will follow up the matter and exact the penalties in all cases.

Next year the Pharmaceutical Congress is to be held at Belfast and the Institute of Public Health at Dublin. The British Dental Association's annual meeting was held in Dublin last week and the attendants had a splendid reception from the citizens. This is but natural when we remember the proverbial Irish hospitality, on which many will count for next year.

The death is announced of the venerable Dr. D. H. Nelson, formerly professor of medicine in Queen's College, Birmingham, and author of various contributions to our literature. He took his M.D. at Edinburgh in 1848. He retired some years ago. He was in the eighty-eighth year of his age when he died on the 10th inst.

The death of Dr. Du Pasquier, F.R.C.S., took place last Friday at the age of eighty-six years. He also had long retired, though he is well remembered by many who knew him when he practised in Pall Mall and was surgeon-apothecary to the Queen and the Prince of Wales.

OUR VIENNA LETTER.

(From our Special Correspondent.)

A CONSERVATIVE MEDICAL POSITION AS TO BICYCLING FOR SEDENTARY PEOPLE—GROWING DISFAVOR OF CHLORATE OF POTASSIUM OWING TO RECENT ACCIDENTS—A BRAIN LESION IN POISONING FROM ILLUMINATING GAS—PROFESSOR ADAMKIEWICZ AND THE PHYSIOLOGICAL IMPOSSIBILITY OF INCREASED INTRACRANIAL PRESSURE.

VIENNA, August 16, 1897.

ABOUT the beginning of the summer most of the bothersome police regulations affecting bicyclists were

done away with. It is no longer necessary to have a police license, or to carry a number prominently displayed, or to appear at the prefecture of police and exhibit your dexterity in riding and mounting and dismounting as a preliminary to the license. While the liberty thus granted has led to a great increase in the number of riders, it has by no means caused the rage for wheeling that was anticipated. For a town of over a million inhabitants, bicycles are comparatively infrequent on the streets of Vienna.

For a good deal of this the doctors are responsible. The profession is extremely conservative here, and the bicycle as a means of exercise does not commend itself overmuch to them. Certain of the older practitioners, when consulted about its advisability by patients, shake their heads dubiously. When a family physician is asked to grant permission for bicycle riding, the examination of the individual is apt to be as complete as if there were question of application for an insurance policy. When there is any symptom of heart trouble permission is at once refused, or allowed only tentatively and with the most careful directions and precautions. If the urine shows any signs of kidney trouble the same result is to be expected. There has been a number of sudden deaths among enthusiastic bicyclists reported from various quarters here in Europe, and hence the medical carefulness. As one of the best-known clinical professors here puts it, it constitutes a form of exercise that is very easily overdone, because the rider only thoroughly realizes his fatigue after dismounting from his machine. After a certain time the habitus of the monotonous motion required for pedalling is acquired by the muscles involved, and they do not give the usual signs of fatigue. General exhaustion readily supervenes, and the wheelman easily exceeds his strength before he realizes it. When there are circulatory or emunctory disturbances already at play, though practically symptomless, they may easily lead to serious consequences as a result of the overexertion and the exorbitant call for additional energy and increased elimination. With regard to the heart, it is clear; as to the kidneys, it has been noted a number of times that if an ordinarily healthy but sedentary individual, in whom, however, there is not the slightest suspicion of kidney trouble, ride with ordinary speed for a couple of hours, blood and some hyaline casts with some traces of albumin may be found in his urine. All this would seem to be the result of sudden call for excessive elimination on organs that were unused to the strain of getting rid of so much waste muscular material at a time. Perhaps the conservatism may not be entirely old fogyism, but be a lesson worth considering when the question of medical advice and direction in the matter comes up.

A recent death from chlorate-of-potassium poisoning here has reawakened the feeling against the drug. It was a simple accident, but it is another warning against lightly prescribing the drug in family practice. During the past winter a well-known actor died from causes that his physician could not explain, and the autopsy showed that it had been chlorate-of-potassium poisoning. Subject to hoarseness and chronic sore throat, he was accustomed to take a certain amount of the drug. During the course of a severer pharyngitis than usual, he sent for a well-known physician, who prescribed chlorate-of-potassium in rather large doses, but so combined as to disguise its taste. The patient continued his own additional doses of the drug, and died by poisoning from it. As the most recent investigations would seem to show that the drug has no specific action in affections of the mouth and throat, and owes its clinical efficacy to its rather limited antiseptic power, it has come into general disfavor here. There are many better antiseptics known now that have not its poisonous properties, and there would seem to be no reason for taking the risks involved in its use. This has come to be considered so rational that there is even question of leaving it out of the next edition of the Pharmacopœia here entirely.

In pathological circles considerable remark has been occasioned by some recent deaths from illuminating gas. The difference in the poisonous properties of the new water gas and the old-fashioned coal gas is enormous. The amount of carbon monoxide — the really poisonous element in illuminating gas — is manifoldly increased under the new system. Water gas is besides almost absolutely odorless, so that no warning is given of its presence. The new gas is supplied in the old pipes and fittings, nearly always leaky, so that there is every reason to believe that small amounts at least of the gas often find their way into the living-rooms of dwellings, and carbon monoxide is one of the gases that even when diffused in extremely small amounts causes symptoms of chronic poisoning. In cases of acute poisoning from illuminating gas here, there is always a spot of brain softening found in the innermost part of the lenticular nucleus near the knee of the internal capsule. This softening is more or less pronounced, according to the length of time that has elapsed between the exposure of the patient to the poisonous gas and the occurrence of death. In cases in which artificial respiration has been employed for a long time and has led to the aspiration into the lungs of large quantities of infectious material from the mouth and nose, the consequent pneumonia may be so fulminant that very little time is allowed for the development of brain degeneration and only its primary stages may be noted. In cases in which the patients fail to recover from their first stupor, it will, of course, be absent entirely; but in all other cases its occurrence is looked for with confidence.

The etiology of the degenerative process is, as usual, a circulatory disturbance. The innermost part of the lenticular nucleus is supplied by a set of minute arteries that come off from the arteriæ fissuræ Sylvii just after the posterior communicating have been given off. They are not usually set down in ordinary anatomical text-books, but it is the interference with the circulation in them which causes the softening. Sometimes they are found thrombosed, sometimes widely dilated. In the latter case Professor Kollisko considers it theoretically probable that the dilatation of the arteries in question, together with the lowered blood pressure, causes such a slowing of the circulation in the important nerve centres involved that the highly organized nervous elements perish from insufficient nutrition.

To those who are interested in the curiosities of medical literature, and to whom pathological and physiological novelties, especially when thoroughly paradoxical, appeal, a recent series of articles from the pen of Professor Adamkiewicz, sometime professor of experimental physiology in the University of Kracow, but now engaged in original investigation in his private laboratory in Vienna, will undoubtedly commend themselves. They have just been concluded in the *Wiener medizinische Wochenschrift*. The professor disagrees and has done so for some time with most of the rest of the world as to the physiological possibility of the occurrence of increased intracranial pressure. The whole diploë is, in his opinion, a large storage reservoir, that acts as a safety valve for the relief of any intracranial pressure above the normal, whenever there is a tendency for that to occur. When the thorax is dilated in respiration, there is a negative pressure produced in the veins of the head and neck, and if there is the slightest increase of pressure within the arachnoidal space or in the millions of canaliculi of the diploë the excess of fluid is aspirated. Experimentally increased intracranial pressure may be produced

by injections into the arachnoid cavity, when a thicker liquid than decinormal salt solution is used, because the bony canaliculæ easily become blocked. Oil, for instance, has been used in such demonstrations, and always with positive results. Using decinormal salt solution, however, Professor Adamkiewicz asserts that it is impossible to produce increased pressure within the brain membranes. Hence his rather startling conclusion, calculated to disturb the even tenor of his way for the earnest but simple seeker for medical truth, "that it is high time to give up the erroneous pathological explanation that certain well-known symptoms are due to increased intracranial pressure, for it is founded on a physiological falsity that cannot but delay the advance of neurology."

IS IT EVER IMPOSSIBLE TO PASS A CATHETER THROUGH THE URETHRA INTO THE BLADDER?

To the Editor of the Medical Record.

Sir: The above question is almost invariably answered in the negative, as it is by Dr. Buckston Browne, in the Medical Record of August 21st. I had a case some years ago in which repeated attempts with instruments of all shapes and sizes failed to secure a passage of the obstruction. The case was of long standing; the perineum was riddled with urinary fistulæ, and I proposed a perineal section. The patient was finally treated by another surgeon, who, as he supposed, passed a sound. He claimed that the sound had entered the bladder and that the stricture had been passed. The patient died on the third day, of acute suppression of urine. At the post-mortem it was found that a false passage, of about two inches in depth, had existed for many years. This false passage was in a direct line with the urethra, and into it all the instruments had passed. The operator had forced his sound through the bottom of this false passage, and by his manipulations had torn up the connective tissue at the base of the bladder. Even after the parts were removed it was impossible to pass the smallest probe through the very short but narrow and tortuous canal which connected the two portions of the urethra. I had worked hours ineffectually on this case before it passed into other hands, and I think it would have been absolutely impossible for any one to pass an instrument through this obstruction, even could the exact condition present have been known.

J. F. Baldwin, M.D.

Cortland, Ohio, August 27, 1897.

TAPEWORM IN MEN.

To the Editor of the Medical Record.

Sir: In the Medical Record of August 28th is an article by Dr. E. C. Chamberlin, on the treatment of tapeworm, in which the author says that he has not seen a single case of tapeworm in a man, and that tapeworm is almost entirely confined to womankind. He quotes the statistics of French military surgeons for ten years, showing only one case in every thirty-six thousand men.

In view of the above statement, it may be of interest to say that during the past seven years of practice in general medicine I have had five cases of tapeworm, all the patients being men. Four of these cases occurred in a town of seven thousand inhabitants; one case in a city of seventy-five thousand inhabitants. Among these eighty-two thousand people there are at least one hundred and twenty-five practising physicians, and several of this number, no doubt, must have found cases of tapeworm in men. The ages of these five men were between twenty-two and thirty-five years, and the specimens passed ranged from twelve to thirty feet in length. No special symptoms were complained of in these cases, the attention of the patients being called by passing segments of the parasites.

John E. Dowling, M.D.

Hornellsville, N.Y.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending September 4, 1897:

	Cases.	Deaths.
Tuberculosis	236	125
Typhoid fever	42	7
Scarlet fever	67	2
Cerebro-spinal meningitis	1	2
Measles	37	5
Diphtheria	119	23
Laryngeal diphtheria (croup)	1	2
Chicken-pox	1	0
Pertussis	2	0

A Curious Case of Hypnotic Suggestion.—A Hamburg practitioner was consulted by a young married lady, who complained of terrible hallucinations, driving her to suicide. She came to him unknown to her husband, who she said was devoted to her, and whom she could not bear to distress by the knowledge of her affliction. Beyond the hallucination complained of, there seemed nothing to indicate mental disease; but a sudden light dawned on Dr. D—— when in the course of further conversation his patient told him of two facts—one that her husband had lately insured her life for a large sum, and the second that he was fond of making hypnotic experiments. Dr. D—— found it easy to hypnotize his patient, but met with obstinate resistance when he commanded her to divulge what had been suggested to her to do. He did not, however, relinquish his efforts, but continued the hypnotic *séances* in the presence of a witness, and at last overcame the resistance of his patient, who acknowledged that her husband had ordered her to commit suicide after two months and to keep his command secret from every one. The insurance company is one that pays even in cases of suicide, if the suicide be committed more than two months after insurance.—*British Medical Journal.*

Health Reports.—The following statistics concerning yellow fever, cholera, small-pox, and plague have been received in the office of the United States Marine Hospital service during the week ended September 4, 1897:

		Cases.	Deaths.
Smallpox.			
Birmingham, Ala.	August 21st to September 1st		
Buckton, Ark.	August 28th to September 1st	1	
Smallpox Foreign.			
Rio de Janeiro, Brazil	[illegible]	4	
Saguia la Grande, Cuba	August 8th to August 15th	8	3
Rotterdam, Holland	August 14th to 21st	2	
Warsaw, Russia	August 7th to 14th		5
St. Petersburg, Russia	August 7th to 14th	7	2
Barcelona, Spain	[illegible]		6
Odessa, Russia	August 7th to 14th	1	
Bombay, India	[illegible] August 3d		1
Cholera.			
Madras, India	[illegible]	1	
Bombay, India	[illegible]		120

PATHOLOGICAL HISTOLOGY OF INTESTINAL END-TO-END APPROXIMATION AFTER THE USE OF THE FRANK COUPLER.

BY JACOB FRANK, M.D.

THE pathology of the reparative process taking place in the intestines after approximation has received but little attention from the various experimenters in this field, it no doubt having been looked upon as of little if any importance. To my mind it is of vast importance, for by microscopical examination only can we obtain accurate and positive knowledge as to how soon and in what manner reparation takes place.

The following is a report on the specimens prepared for me by Dr. Fred C. Zapffe. All the specimens with the exception of one, in which Murphy's button was used, were obtained from dogs operated upon with my decalcified bone coupler, used in the manner as already published in the MEDICAL RECORD of October 3, 1896.

Section Removed Ten Days after Date of Operation (Fig. 1).—Macroscopical appearance: There is no adhesion or matting of the intestines and the point of approximation can be found only by running the bowel through the fingers, when a slight ridge is felt.

FIG. 1.—After Ten Days (Frank Coupler).

There is a little thickening of the bowel at this point. On the inner surface of the bowel, projecting over the mucosa, is a smooth line marking the point of union.

Microscopical appearance: All the layers are in juxtaposition.

Mucosa: This is somewhat thickened and the ridge above mentioned is seen. This ridge has no villi, nor does it in the least resemble normal mucosa; it consists entirely of small, round, inflammatory cells, closely packed. On either side the normal mucosa is seen, but no attempt at regeneration of the villi.

Muscularis mucosæ: The ends are separated; the gap is filled in with connective tissue.

Submucosa: It is thickened at the line of union,

FIG. 2.—After Sixty Days (Frank Coupler).

but is continuous. It is very vascular. The blood-vessel walls are also thickened.

Muscularis: The circular and longitudinal coats are distinctly cut off at the line of union. The cut ends present some proliferation of the muscle cells, but the muscles have not united, the gap being filled in with a loose, very vascular connective tissue.

Serosa: This coat is very much thickened and very vascular. The new-formed tissue is easily distinguished from the old by these features. The connective tissue is very loose, having the appearance of a network of mesh.

Section Removed after Sixty Days (Fig. 2).—Macroscopical appearance: No adhesions or matting of intestines are found. The point of operation is hardly distinguishable. A slight line is felt at the line of union. There is very slight contraction of the lumen of the bowel, the index finger passing easily. On the inner surface of the point of union is a slight groove. The lymphatic and blood vessels run across the line, giving the bowel quite a normal aspect.

Microscopical appearance: The various layers are in perfect juxtaposition. Continuity has been established in every layer except the muscular, and regeneration has been established in the mucosa, submucosa, and serosa.

Mucosa (Fig. 4): The mucosa is continuous and shows no formation of new tissue, being unchanged. There is at the site of union a falling inward of the villi, an entropion, as it were, due probably to the cicatricial contraction of the scar tissue beneath. The tops of the villi thus drawn down meet with those of the opposite side, presenting an appearance as though they had been piled up. There is no connective tissue formed between the villi.

Muscularis mucosæ has not become continuous, the ends of the cut muscle being separated by scar tissue.

Submucosa has an almost normal appearance. It is continuous and regenerative, although it is slightly

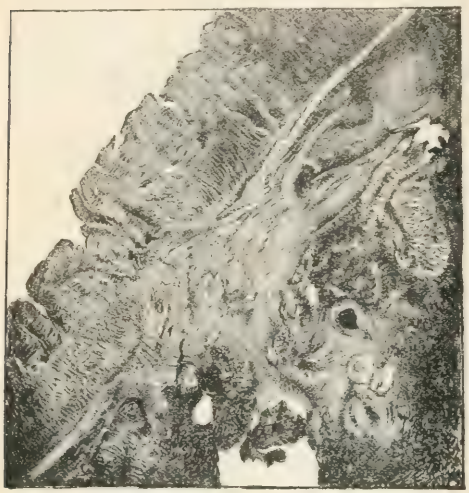

Fig. 3.—After Sixty Days (Frank Coupler).

thickened. Blood-vessels are prominent, being also thickened.

Muscularis: The outer layer is united by connective tissue, into which a few muscle fibres project from either side. There is, however, no regeneration. This layer is closely applied to the serous layer. The ends of the inner layer are nearly in apposition, and look like spindle-shaped processes. Connective tissue connects them, and no muscle fibres can be seen projecting into it as in the other layer. Although there is some proliferation of the muscle cells in the cut ends, there is no regeneration. The connective-tissue fibres on each side of the line of union run from the muscular to the serous layers, thus forming two bundles, the fibres interlacing as they cross.

Serosa is thickened and more vascular than normal. The cicatricial tissue is distinguishable at the line of union, and is arranged as above mentioned.

Two Specimens Removed after Sixty Days.—The macroscopical appearance was the same in both.

Microscopically the first specimen, Fig. 3, differs somewhat from the second, Fig. 2, in that the gap in Fig. 3 is wider than in Fig. 2, in which the layers are almost in apposition. This is due to the different method of preparation—Fig. 3 specimen being stretched on cork with pins; Fig. 2 specimen not so.

Section Removed after Ninety Days (Fig. 5).—Macroscopical appearance: There are no adhesions between omentum and bowel or loops of bowel. Site of operation hardly distinguishable, except for a slight line which is felt. Appearance of bowel is normal. On the inner surface hardly anything is seen to indicate an operation. The lymphatics and blood-vessels cross the line of union and are readily discernible. Bowel is patulous and but slightly contracted, the finger passing easily.

Microscopical appearance: There is little difference between this specimen and the previous one. The scar has contracted more than in Fig. 2, which has brought the different layers into closer apposition, making it almost impossible to distinguish the line of union. The mucosa and submucosa have the same appearance as in Fig. 2. The muscularis mucosæ is also the same. The muscularis has not regenerated and presents the same appearance as in the previous section, as does the serosa.

Section Removed after Sixty Days, Murphy Button (Fig. 6).—A Murphy button was carefully introduced in a large healthy dog and the section removed after sixty days. The mucosa, muscularis mucosæ, and submucosa have the same appearance as in the specimens obtained from my coupler; so also the muscularis and serosa. On the whole, this specimen varies but slightly from the specimen produced from the coupler, the difference being that the ends of the muscularis are in closer apposition in the coupler specimens than in the button specimen. There is no regeneration of muscle in either instance, connective tissue intervening between the ends.

The following is a report furnished by Dr. Evans, pathologist of the College of Physicians and Surgeons:

Section Removed after Eleven Months (Fig. 7).—Report of autopsy on large Newfoundland dog, held Sunday, May 2, 1897.

Present, Drs. Frank, Kunz, and Evans.

The old dog was fat and healthy looking. The line of abdominal incision showed union without adhesions of the underlying viscera.

The intestines showed no evidence of old peritonitis. The point of operation was found 2.6 cm. from the cæcum. There was no distention of the bowel above the point of operation. The omentum is attached at two places. One is over the line of union; the other is 1 cm. therefrom. Each is slight and inconsequential; over the scar the peritoneal coat lies evenly. The blood and lymph vessels are continuous from one side to the other.

When the post-mortem was made, the intestines were still in motion, and it was noticed that the line of union caused a break in the muscle wave.

Intestine *in situ* unopened: There is noticed a V-shaped indentation over the free side of the intestine;

Fig. 4.—Appearance of the Mucosa after Sixty Days (Frank Coupler).

this is about 0.2 cm. in depth. It is not appreciable over the remainder of the intestine. Around the intestine is a linear scar. In the mesentery, 0.2 cm. from the intestine, is an oval mass about 1 cm. in diameter. Over it the peritoneum glides smoothly. The mass is

joined in the scar by a line of scar tissue. This piece was removed for microscopic examination.

Intestine removed, unopened. The finger gently passed through the lumen, appreciated the line of union as a thread-like band, giving the sense of resistance to expansion rather than decrease of lumen.

Intestine removed, opened: The mucosa is continuous over the line of union. Cross-section over the scar shows that in places there is a slight projection into the lumen. In places there is a slight furrow. In the submucosa and muscular tunics there is a narrow band of connective tissue.

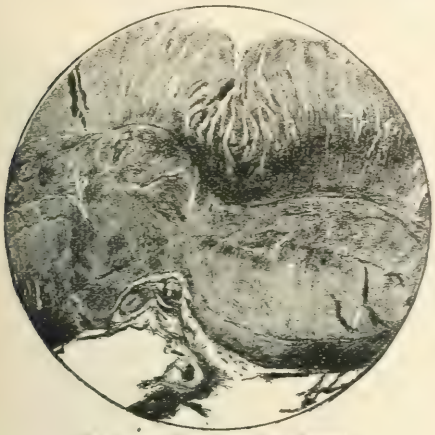

Fig. 3.—After Ninety Days (Evans Coupler).

The sections for microscopic examination were made longitudinally. They were from two places: one from the distal, the other from the proximal side. In some sections there is a wedge-shaped depression that is about 0.6 mm. in depth. In others there is a pyramidal elevation that rises 0.75 mm. Mucosa is joined to mucosa, muscularis to muscularis, etc.

Mucosa: This coat is continuous over the scar without a break. The epithelial glands, the villi, and the cells themselves are absolutely unchanged. The muscularis mucosæ runs into the cicatricial tissue.

In the area of circular muscular fibres the scar reaches its greatest breadth. It is here 0.8 mm. broad. In the longitudinal muscularis it is less broad.

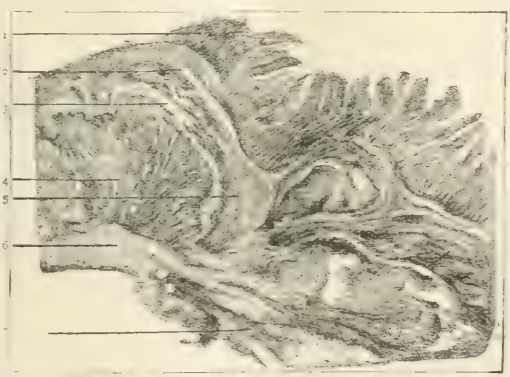

Fig. 4.—After Eleven Months (Evans Coupler). 1, Mucosa; 2, muscularis mucosæ; 3, submucosa; 4, inner circular muscle; 5, scar tissue; 6, outer longitudinal muscle; 7, serosa.

Scar: The connective-tissue fibres run from the serous coat to the muscular coat; generally they are in two groups, with what appears to be some old tissue remnants between the two bundles. The direction of the fibres has a bearing on the question of subsequent contraction. The fibres are as old, dense, and free from nuclei as one would expect in inflammatory connective tissue that is a year old. In this area, and especially near the summit, the region corresponding to the old submucosa, there is an abundance of blood-vessels. Their direction is generally circular. Their walls blend intimately with the surrounding tissue. That transudation is not accurately balanced is shown by some serous infiltration of these fibres.

There is some inflammatory thickening in the serous coat. No sutures were found. Nodule from mesentery; this is a mass of inflammatory tissue. In the centre is a silk suture.

Dr. G. Fütterer, who also examined the microscopical sections, fully agrees with Drs. Evans and Zapffe in their reports as given to me.

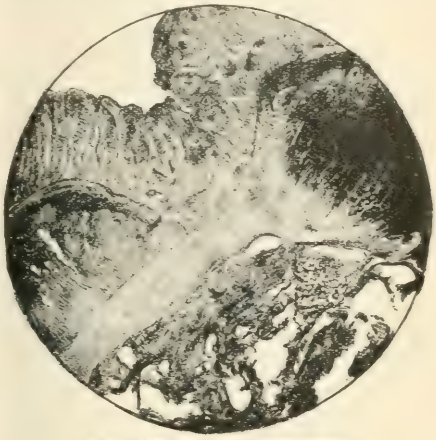

Fig. 5.—After Sixty Days (Murphy Button).

Conclusions.—From the microscopical examinations made by Professor Evans and Dr. Zapffe, and from their reports given to me, I have come to the following conclusions: That the mucosa in all the specimens shows an entropion, which is an entirely passive occurrence and is due solely to the contraction of the underlying scar tissue. There is a complete regeneration of the mucosa.

Garbarini, who did the microscopical work for Dr. Achille Boari, of Italy, in October, 1896, after the use of his modified Murphy button, states that there is no regeneration of the mucosa.

Dr. Hektoen, who reports the microscopical work for Dr. Murphy after the use of his button, claims a complete regeneration of the mucosa.

Submucosa: This coat has become more vascular and denser at the point of union, otherwise presenting no change from the normal.

Muscularis: Quite a difference of opinion exists as to whether or not complete regeneration takes place in this layer.

In all the specimens prepared for me by Professor Evans and Dr. Zapffe there was no restitution or regeneration of the muscular coat. At the cut ends of the muscle some proliferation of muscle cells and an attempt at regeneration invariably take place, but I believe that the connective tissue, like a weed, fills up all interspaces, forming and growing so rapidly as to replace and crowd out the more delicate structures, thus preventing their further growth. There is no question as to the proliferation of the muscle cells in the ends of the cut muscle, but it is insufficient to fill out the gap.

Owing to the pressure of the coupler, some muscu-

lar fibres are no doubt separated from the others, and the connective tissue then growing between them forces these detached fibres out into the body of the scar. It certainly is no attempt at regeneration.

Dr. L. Hektoen, in his report on Dr. Murphy's button-operation sections, states that after thirty days the longitudinal muscular coat can be said to be almost restored, and the transverse muscular completely united by connective tissue. In describing the section which was removed after sixty days, Dr. Hektoen says that the longitudinal and circular muscular layers are continuous and not distinguishable from those in the normal intestine, except that they contain some small spaces (blood-vessels) and occasional traces of fibrous tissue.

I must differ with Dr. Hektoen, as I have not found this condition in any of my specimens nor in that made with the Murphy button on a dog killed sixty days after operation. The most conspicuous part of the scar is the non-regeneration of the muscular coats, and it is the feature which at once attracts one's notice upon looking at the section through the microscope. Dr. Hektoen further says that, were it not for the thickening described in the submucosa and muscularis mucosæ, it would be difficult if not impossible to recognize the line of union.

The submucosa beyond question is thickened, but not so much so as to make it a prominent feature; and as for the muscularis mucosæ, it, like the muscular coats, has not united at all—hence is not regenerated.

If a section after removal is at once placed into Fleming's solution and left there for twenty-four hours, then washed well in running water, followed by immersion in ninety-five-per-cent. alcohol, each layer of the bowel can be distinguished with the naked eye, and your attention is directed to a white band, the muscularis, which is intersected by a dark line. This is the scar tissue. Microscopic examination verifies this. The dark intersection is also seen in the muscularis mucosæ. The submucosa, being in itself connective tissue, does not show this.

I do not question that some muscular fibres may grow out into the scar and meet, but they are not sufficient in number to call the process a regeneration. Even this is not found in any of my specimens, nor in Murphy's. The cutting of the muscular coats acts as a stimulus and the result is a proliferation in the cut ends, but the connective tissue grows far too rapidly to permit a regeneration.

Among the influences which increase the capacity of proliferation of the cell and which lead to a new formation of cells, increased nutrition brought about by a hyperæmia plays an important part. This in a degree explains why the mucosa regenerates, being so highly vascular.

I am now making experiments with various suture methods, in order to ascertain what difference if any exists in the process of repair. The results of this work I will publish later on.

Serosa: This layer is invariably united perfectly and is closely applied to the muscularis. Owing to the irritation and reaction resulting therefrom, it is considerably thickened and more vascular, but otherwise presents no change.

As mentioned in the microscopical reports, the fibres of the cicatricial tissue take a direction from the serosa on one side of the line of union to the muscularis on the opposite side, thus forming two bundles or groups of fibres, which interlace and form a network. This has an important bearing on the subject of contraction and narrowing the lumen of the bowel. The fibres not only pull the ends of the bowel together, but also the muscularis and overlying tissues toward the serosa on the one hand, and the serosa toward the muscularis on the other. If these fibres ran around the bowel in the same direction as the circular muscular fibres, a contraction would result; but this cannot take place when the fibres run in the opposite direction. There is at the same time a thinning of the wall of the bowel as the fibres pull both toward serosa and mucosa.

I am greatly indebted to Mr. W. G. King for his kindness and labor in preparing the photographs from the microscopical sections.

17 [illegible]

THE RISE AND PROGRESS OF DERMATOLOGY.*

BY MALCOLM MORRIS, F.R.C.S. EDIN.,

[illegible]

THE present is a time of jubilees and centenaries—occasions which we, in common with toilers in other fields, celebrate by reviewing the progress that has been made, and giving thanks to God that we are not as our predecessors were a hundred or even fifty years ago. The custom might at first sight seem to have a tendency to engender a feeling of Pharisaic self-complacency. In reality, however, such retrospects have a chastening effect, as showing that, if we have any reason to look upon ourselves as just in a scientific sense, this is largely the result not of our own merits but of those of the men who prepared the way for us. They have the still greater advantage of enabling us to see exactly where we stand in knowledge of the things which form the object of our study, by showing us what has been done and what yet remains to do. As embryology furnishes the key to the riddles of anatomy, so the history of the evolution of any branch of science throws light on many points that would otherwise be dark, explains the origin of terms and theories, rescues from oblivion truths overlooked or forgotten, and, showing the pitfalls which hindered those who have gone before, teaches us to walk more warily.

It is remarkable that in the journalistic pæans in which the triumphs of medicine in the glorious reign of Queen Victoria have lately been recounted dermatology has had no part. Why should this branch of our art be thus unhonored and unsung? It is a form of specialism, no doubt; but specialism is no longer looked upon as an unclean thing—except here and there by some survivor of an antique world. Dermatology, although its victories have perhaps been less showy than those won in some other special departments, has not lagged behind in the onward march of medicine. It has therefore seemed to me that I might on the present occasion fitly endeavor to supply the missing chord in the great *jubilate* whose echoes are still ringing in our ears. A review of the progress that has been made in the knowledge of skin diseases is all the more appropriate at the present time, since what I take leave to call the centenary of the birth of scientific dermatology is not long past. In 1790 the Medical Society of London awarded the Fothergillian gold medal to Robert Willan, who had some time before submitted to it the outline of his plan for the arrangement and description of cutaneous diseases.' Willan may justly be called the creator of dermatology. Before him the skin was looked upon more as a mirror on whose face internal disease "glassed itself in tempest" than as an important organ subject to manifold disorders peculiar to itself. A review of the development of this branch of medicine during the

* An address delivered at the opening of the section of dermatology at the annual meeting of the British Medical Association, Montreal, September 1, 1897.

past hundred years is therefore virtually a history of it from its beginning. This, of course, cannot be told in detail here, although a full record of the work of the makers of dermatology would certainly not be lacking either in interest or in usefulness. All that can be attempted in the time at my disposal is a rapid sketch of the principal changes in the conceptions of skin diseases and in the manner of treating them that have taken place since Willan reclaimed this waste land of pathology and brought it under scientific cultivation.

Forerunners of Willan.—Willan was not the first who wrote on skin disease. As our terminology bears witness, the Greeks gave a good deal of attention to the subject. Hippocrates speaks of "pityriasis," "lichen," "herpes," "pomphi," and many other forms of cutaneous lesion, and roughly classifies them. Later Celsus, Galen, Paul of Ægina, and after them the Arabians, described various affections of the integument. The mediæval writers might have said with Browning's *Karshish*:

> "Scalp disease
> Confounds me, crossing so with leprosy."

Much of the skin disease they saw was leprosy, and they doubtless often imagined it where it did not exist. At a later period syphilis overshadowed everything.

The first treatise professedly devoted to diseases of the skin was that of Hieronymus Mercurialis, of Venice, which was published in 1572 under the title, "De Morbis Cutaneis et de Omnibus Corporis Excrementis." The author had, however, nothing to teach beyond what he found in the ancient writers. In the early part of the eighteenth century Daniel Turner produced "A Treatise of Diseases Incident to the Skin," which appeared with the *imprimatur* of the president and censors of the Royal College of Physicians of London, to whom it was offered in an "Epistle Dedicatory" in 1712. Turner's work, though it is described by Kaposi as "very important," is almost wholly a compilation from other writers, and treats not of the skin alone, but of all "distempers" affecting "the outward Parts or Confines, as may be said, of the Human Body." Thus, not only the eruptive fevers, the "green sickness," and the "yellow jaundice," but phimosis and paraphimosis, hemorrhoids, "chaps on the fundament," imperforate conditions of the natural passages of the body, ulcerations of all kinds, burns, stings, and bites of venomous creatures, hydrophobia, and poisoned wounds are looked upon by the author as falling within his province.

Later in the same century there appeared almost simultaneously two works, each of which in its own way marked a distinct advance toward a scientific dermatology. In a book entitled "Doctrina de Morbis Cutaneis," which was published at Vienna in 1776, Joseph Jacob von Plenck for the first time attempted a complete classification of diseases of the skin. He arranged them, according to what appeared to him to be the most characteristic objective feature, in fourteen groups with one hundred and twenty varieties. In his "Tractatus de Morbis Cutaneis, published in Paris in 1777, Lorry, besides giving good descriptions of clinical phenomena, discussed the pathology of cutaneous affections in the light of the knowledge of the structure of the skin and the morbid processes of which it might be the seat as they existed in his day.

But these were voices of men crying in the wilderness, and neither Plenck nor Lorry—meritorious as were the works of both—did much to dissipate the darkness that was upon the face of this branch of medicine. At the beginning of the nineteenth century it could be said with perfect truth that little improvement had been made in the subject at large since the days of Avicenna.[2]

The Birth of Dermatology.—In 1808 there appeared the first volume of Willan's treatise "On Cutaneous Diseases," a great work, which its author did not live to complete. Ten years before, he had given to the world a slender volume dealing with a particular class of lesions of the skin.[3] Willan set himself the task of reducing the chaos of skin diseases to something like a cosmos. The following, to quote his own words, are the objects at which he aimed in the execution of this design:

"1. To fix the sense of the terms employed by proper definitions.

"2. To constitute general divisions or orders of the diseases from leading and peculiar circumstances in their appearance; to arrange them into distinct genera; and to describe at large their specific forms or varieties.

"3. To classify and give names to such as have not been hitherto sufficiently distinguished.

"4. To specify the mode of treatment for each disease."

Like Plenck, Willan grouped skin diseases according to the character of the predominant lesion; and indeed there can be little doubt that he took the groundwork of his classification from Plenck.[4] The English dermatologist, however, reduced the fourteen orders of his Austrian forerunner to seven, "to be characterized by the different appearances of papulæ, scales, rashes, vesicles, pustules, tubercles, and maculæ." To these another order, "bullæ," was afterward added. This classification is of course very defective, inasmuch as it takes account only of the outward and visible signs and results of disordered action. As the skin has but a limited range of pathological expression, lesions identical in appearance and in structure are produced by widely different causes. Hence a classification based solely on objective appearances inevitably led to the formation of motley groups including conditions having no essential feature in common; wherein, for instance, variola was classed with scabies as being "pustular," and varicella with eczema as "vesicular," diseases. Moreover, as in the evolution of many affections of the skin the lesions run through almost the whole gamut of differences in appearance which constitute the several "orders," it is unsafe to look only at them in seeking for the distinctive characters of such diseases. But Willan's classification, defective as it was, at least introduced a definite principle of arrangement into a region of pathology where before all was "most admired disorder." If he got the idea from Plenck, he must be allowed the credit of having greatly bettered the instruction which he received, and of having presented it to the medical world in such a manner as to impress it on the mind of the profession.

It is not, however, Willan's classification that constitutes his chief title to be regarded as the founder of dermatology. His judicious selection and accurate definition of terms; his astonishingly faithful word pictures of the appearances of disease, drawn directly from nature, and made more vivid but scarcely more graphic by the colored engravings with which he supplemented his descriptions, and his rational methods of treatment, were all his own. It was his teaching that transformed a confused jumble of folklore as to "tetters," wet and dry, and of figments of the medical imagination, embodied in words of learned sound but little meaning, into a science, rudimentary indeed, but grounded on a solid foundation of observed fact. Willan's work is, therefore, rightly looked upon as the true starting-point in the history of dermatology.

The English School.—Willan died before he could complete his work; but, fortunately, he left behind a disciple well worthy to wear his mantle. This was Thomas Bateman, who had been in constant intercourse with him for many years, and who was thor-

oughly acquainted not only with the teaching but with the spirit of his "learned preceptor." Bateman completed Willan's unfinished "Delineations of Cutaneous Diseases," and published a "Practical Synopsis of Cutaneous Diseases," which did far more to make his master's work known than Willan's own unwieldy and incomplete book. It is hardly too much to say that without Bateman Willan might have been forgotten. Bateman, however, was not a mere expositor; he was a man of truly scientific mind, and would doubtless have added largely to knowledge had not he, too, been cut off prematurely.

Bateman's "Synopsis" ran through several editions in his lifetime, and afterward found an editor in Anthony Todd Thomson, who also published an "Atlas of Delineations of Cutaneous Eruptions" illustrative of the descriptions in Bateman's book. Thomson paid special attention to diseases of the skin for more than thirty years. He was an accurate observer, and was very successful in treatment. Toward the end of his life he embodied the fruits of his experience in a "Practical Treatise on Diseases Affecting the Skin," which, however, he did not live to finish; it was completed by his nephew, Edmund Alexander Parkes, who was familiar with Thomson's opinions and methods of treatment in cutaneous diseases, and published in 1850. Thomson held that there could be "scarcely any difference of opinion respecting the necessity of arranging the tribe of those diseases . . . [of the skin] according to the physical characters of the eruptions," and in adopting this method he chose "as the least exceptionable the orders of Willan."[5] But although "forced," as he says, to adopt the arrangement, he was careful to guard himself against the supposition that he regarded "the knowledge of their physical characters as throwing any light upon the nature of the diseases which originate the eruptions."

Thomson was physician to University College Hospital, where he was the first of what may be called a dermatological succession, which, handed on in turn by Parkes, Hillier, and Tilbury Fox, is still worthily continued by Radcliffe Crocker.

Almost simultaneously with the treatise of Thomson and Parkes there appeared a work which is one of the landmarks in the history of the English school of dermatology. This was Erasmus Wilson's "Diseases of the Skin," the preface to which is dated 1851. Wilson, who had commenced his scientific career as an anatomist, had already done a good deal of work in dermatology, particularly in the microscopic study of the cutaneous tissues. He made a new classification of skin affections, grouping them, according to the structure in which the morbid process originated, into four primary divisions: (1) Diseases of the derma; (2) diseases of the sudoriparous glands; (3) diseases of the sebiparous glands; (4) diseases of the hairs and hair follicles. Each of these included numerous secondary divisions, corresponding to the manner in which the structure was changed or the function disordered. Wilson's influence was for a long time predominant among his own countrymen, and by workers in other countries he was looked upon as the foremost representative of British dermatology. He had an eye for form and color, and often found the right word to express them. His description of diseased conditions are thus almost unrivalled in their picturesque and yet faithful rendering of appearances. He added little, however, to our knowledge of the pathology and therapeutics of skin diseases, and added not a little to the confusion which existed on the subject, by his artificial classification and his ever-changing nomenclature.

On the work of the living leader of our British school of dermatology, Mr. Jonathan Hutchinson, it is not fitting to dwell here. It may, however, be permissible to say that he has brought to the study of the pathology of the skin a knowledge of disease in general such as probably no other dermatologist has ever possessed. This, together with a marked originality and independence of mind, and a singular power of seeing points of likeness in things to outward seeming most unlike, has enabled him to throw an unexpected light on many dark places of dermatology.

On the whole it may be said that the characteristics of the British school of dermatology are those commonly held to be distinctive of the British intellect in whatever sphere it is set to work. We are a practical people, loving facts and caring little for theories. Accordingly British dermatologists from Willan to Hutchinson have been first of all observers. They have striven to get at what Magendie called the *fait brut*, to see things as they really are, and to describe what they saw as faithfully as they could. They have been distrustful of generalizations and cautious—perhaps overcautious—in deductions. But the facts gathered by them have endured while theories and systems have followed each other into nothingness; and dermatology as it exists to-day is largely the work of their hands.

The French School.—In France a school of dermatology arose independently in the early years of the century. In 1808 Alibert published his "Description des Maladies de la Peau observées à l'Hôpital Saint Louis," which he followed up two years later by a "Traité Théorique et Pratique des Maladies de la Peau," and several other works. The most valuable part of his publications was the illustrations; his writings only added to the darkness in which the whole subject of diseases of the skin was then enshrouded. His terminology was to the last degree confusing, his classification was arbitrary, his descriptions were often fanciful. Yet he contributed to the advance of knowledge by directing the attention of more scientifically minded workers to the subject. Among these was Biett, who adopted Willan's classification with some modifications and introduced it into France. Biett taught for many years at St. Louis, but the only record of his observations and experience is contained in the "Abrégé Pratique des Maladies de la Peau" of his pupils Cazenave and Schedel, which appeared in 1828. Yet, though he published nothing in the ordinary way, his teaching had a much more far-reaching influence than that of Alibert. In 1831 Rayer sketched out a plan of classification of skin diseases on a basis of morbid anatomy, dividing them into: (1) Inflammations; (2) morbid secretions; (3) congestions and hemorrhages; (4) anæmias; (5) neuroses; and (6) deformities—thus anticipating Hebra in principle and, to a considerable extent, in detail. Rayer's work is a mine of information as to the early literature of dermatology, and embodied the results of extensive clinical observations so accurate and so clearly recorded that much of it is of permanent value.

Among the leaders of the French school who followed Biett were Cazenave, Gibert, Devergie, and Bazin, all of whom did something to advance the knowledge of skin diseases, though they were apt to let themselves be misled by a tendency to erect systems on unsound foundations. To them skin diseases were, for the most part, the expressions of some constitutional dyscrasia, which at best was an unnecessary hypothesis, and was sometimes, as in the case of the so-called "dartrous," "psoric," and "herpetic" diatheses, a myth. Indeed, it may be said that in France dermatology was the "last ditch" in which these mediæval notions still fought for life. In recent years the yoke of the diatheses has been shaken off, and the labors of Hardy, Vidal, Besnier, and Brocq have placed the French school in the forefront of scientific dermatology, a position which, with such men as Darier, Thi-

bierge, Wickham to take the place of their seniors when they have to fall out of the ranks, it is in no danger of losing.

The German School.—The year 1844 marked the beginning of a new era in the study of diseases of the skin, for it witnessed the first appearance of Ferdinand Hebra before the scientific world. That remarkable man breathed a new life into the dry bones of dermatology, and set it on a path of progress which has already led to great results. Hebra applied to the investigation of skin diseases the pathological teaching of Rokitansky. He classified them, not according to their objective appearances, or to the structures supposed to be primarily or mainly affected, but according to the nature of the pathological processes of which they were examples. He used the experimental method, producing various lesions on healthy skin by artificial means, and observing the changes which they underwent when allowed to run their own course, and when modified by treatment of different kinds. In this way Hebra rationalized dermatology, ridding it of the superstitions as to dyscrasiæ with which it had before been infested, and giving to the treatment of skin disease a directness of purpose and a simplicity of means undreamt of by his predecessors. Students of skin disease flocked from nearly every part of the world to sit at the feet of the Vienna Gamaliel, and the influence of his teaching was felt everywhere except in France, where, as has been said, the traditional belief in dyscrasiæ persisted till a comparatively recent period. Hebra's work has been carried on by Auspitz, Kaposi, and Neumann in Vienna, by Pick in Prague, Schwimmer in Budapest, Lewin and Lassar in Berlin, Neisser in Breslau, and many others.

If Willan was the creator, Hebra must be acknowledged as the greatest among the reformers of dermatology. This glory must be his in spite of the fact that his classification in its leading features had been anticipated by Rayer. Hebra, however, worked it out so fully as to make it his own; and his classification, though it has necessarily been modified as knowledge grew, notably by the influence of Virchow's "cellular pathology" and by the newer bacteriological doctrine, can never be superseded till an arrangement based on etiology becomes possible. Such a classification has already been attempted by Auspitz and after him by Bronson, but the time for it is not yet.

The American School.—The history of dermatology in America has been written by Prof. J. C. White, of Harvard, and by Prof. Louis A. Duhring, of Philadelphia, from whom all that can here be said on the subject is taken.[6] For the first thirty years or more of the century little or no interest in cutaneous affections was taken in America. A story is told which, whether true or not, serves to illustrate the state of things in these days. A student, asking a physician for information as to a disease of the skin, was met with the reply: "Sir, I know nothing of skin diseases; you must go to a surgeon." On his applying to the surgeon, the answer was: "Sir, I must refer you to the physician." In fact, as Duhring tells us, a disposition existed to consign the whole of this branch of medicine to those outside the professional pale. No one seemed prepared to take up the matter. Still, even at that period, there was a demand for information on skin diseases which booksellers thought it worth while to supply. Bateman's "Synopsis" was republished at Philadelphia in 1818, a second edition being issued in 1824, and a translation of the work of Cazenave and Schedel appeared in the same city in 1829, a second edition being published in 1832. In 1845 appeared the first American work on dermatology. It was entitled "A Synopsis of the Symptoms, Diagnosis, and Treatment of the more Common and Important Diseases of the Skin," and its author was N. Worcester, professor of physical diagnosis and general pathology in the Medical School of Cleveland. The book is described by Duhring as being little more than a compilation from the works of the French and English dermatologists of the day.

Meanwhile, other signs of a growing interest in the subject were not wanting. In 1836 an infirmary for diseases of the skin was opened in New York, it being the first institution of the kind established in the United States, and lectures on skin diseases were delivered there, and afterward in some of the medical schools of New York between the years 1837 and 1854 by Dr. H. D. Bulkley, father of Dr. L. D. Bulkley, whose name is well known to all dermatologists.

At this time Paris was the centre of the dermatological world, and American students accordingly went there for instruction in the subject. Hence for many years American dermatology was the direct offspring of the French school, the influence of which was only slightly tempered by reprints of the works of Wilson and other English writers. At a later period Americans flocked to Vienna, and on returning home spread the doctrines of Hebra among their countrymen. As early as 1859 Hebra's teaching was made known in America by Prof. James C. White, who, two years later, at Harvard gave the first course of lectures on diseases of the skin. After the civil war clinical lectureships on the subject were established in several important schools. In 1870 the foundation of the *American Journal of Syphilography and Dermatology* did something to promote the advancement of the knowledge of skin diseases in America, and the establishment of the American Dermatological Association in 1877 gave a powerful impulse in the same direction, which was further aided by the creation of the *Archives of Dermatology*. Yet in 1871 Prof. James C. White complained that as yet America had contributed little to dermatology, and that this branch of medicine had hardly then found a place among his countrymen as an acknowledged specialty. Now this reproach has been wiped away, and American dermatology, represented by Duhring, J. C. White, Bulkley, and others, is recognized as being in the van of progress.

The Fusion of the Schools.—Each of the three great schools which helped to lay the foundations of modern dermatology had certain marked characteristics. The English was essentially clinical, using classification only as a practical help in diagnosis; it observed. The French systematized, striding somewhat impatiently over facts to get at general formulas, which, though plausible on paper, too often broke down in application. The German was pathological, giving attention mainly to the mechanism and occasionally taking too little heed of the causes setting it in motion. Each school had thus the defects of its qualities; but each played an important part in the development of dermatology, and much of what was good in each still survives in the cutaneous medicine of the present day.

Now dermatology is truly international, the different schools which were formerly as separate States having become fused into one scientific commonwealth. This has been accomplished by the translation of representative works of each school into the language of the others; by the multiplication of journals devoted to this special branch of medical science, in which everything of value that is published in any part of the world is gathered up and summarized; by the facilities of communication, which make it easy for the scientific pilgrim to visit every dermatological shrine where his devotion is likely to be rewarded with knowledge of some new thing; and by congresses, those marts for the exchange of scientific wares which have so powerfully aided in the diffusion of knowl-

edge, in the extinction of national jealousies, and in the correction of provincial ways of thought. Dr. Johnson when at Oxford was overheard to say that he had a mind to see what was being done in foreign universities, "for an Athenian blockhead is the worst of blockheads." He thus vigorously expressed the truth that a man trained in a particular school is apt to be narrow if he knows nothing of any other. In the sphere of dermatology this kind of narrowness was especially exemplified in the French school, but neither of the others was entirely free from it. How could it be otherwise when they knew so little of each other? How slowly the work even of so brilliant a dermatologist as Hebra became known to the profession in other countries at a time comparatively recent is shown by the following passage which I quote from Prof. James C. White. Speaking of the middle of the fifties he says: "It was not until the intelligence began to spread, slowly borne by word of mouth from country to country, that in an imperial city of Austria there was a man teaching skin diseases as they had never been taught before, with unlimited means of clinical illustration, with the keenest eye for observation, with an unbounded amount of information drawn from many years of experience, with a self-restraint which no desire for premature fame could tempt into hasty publication, and with a sound and logical mind, that the German school of dermatology some fifteen years ago began to be known and to advance to that pre-eminent position it now holds."[7] Fame flies faster nowadays, but the very ease and rapidity with which the results of a man's work can be made known now lead to the publication of much that is inaccurate observation and immature speculation.

Progress in Knowledge.—Turning now from the workers to the work that has been done, the most striking feature of the dermatology of to-day as compared with that of the beginning of the century is the knowledge of the nature and causes of skin diseases that has been gained. Willan and Bateman left little in the way of outward appearances for those who came after them to describe, but no real knowledge of pathological processes was possible till the microscope and other modern methods of research were applied to the study of diseases of the skin. This is the special achievement of the German school. The attention directed to processes has led us to recognize that many conditions which used to be looked upon as distinct affections are really different stages in the evolution of one and the same disease. In this way dermatology has been greatly simplified. Compare, for instance, the modern teaching as to eczema with that of Erasmus Wilson, with his six principal varieties—erythematosum, papulosum, vesiculosum, ichorosum, pustulosum, squamosum; and his ten subvarieties—marginatum, fissum, mucosum, scabidum *seu* crustaceum, œdematosum, tuberculosum, spargosiforme, sclerosum, verrucosum, neurosum. Then, according to the parts attacked, there was eczema capitis, faciei, auriculare, mammillare, umbilicale, perineale. The varieties of psoriasis were still more numerous—punctata, guttata, alphoides, nummularis, scutellata, orbicularis, annulata, circinata, vulgaris, gyrata, circumscripta, diffusa, confluens, discoidea, centrifuga, imbricata, figurata, inveterata; with the local forms—palpebrarum, labialis, præputii, scrotalis et pudendalis, palmaris, unguium; it is like the catalogue of the ships that bore the Danaans to Ilios. And for a long time nearly every writer on skin diseases thought it due to himself to show his inventiveness in the same way. It is no wonder that dermatology treated in this way was a terror to students and an affliction to practitioners.

Further simplification has resulted from our having learned to distinguish between the primary lesions which are the notes of a particular disease and the lesions which result from secondary causes, such as injury from scratching or rubbing and the invasion of pyogenic micro-organisms. Much confusion and needless multiplication of types were caused in former days by mistaking the accidental for the essential in such affections as scabies, eczema, ringworm, impetigo, and other conditions liable to complication by suppurative processes.

Pathological research has done much to elucidate the nature of growths, benign and malignant, of the skin. The work of Jacob Warren, Hutchinson, Dubreuilh, and Norman Walker in regard to rodent ulcer and that of Kaposi in regard to sarcoma of the skin and xeroderma pigmentosum mark distinct advances.

Real progress in the science of medicine, however, is measured by the increase in our knowledge of the causes of disease. In this respect it may, I think, be said that as much has been done in dermatology as in any branch of medicine. The etiology of a very considerable proportion of skin diseases is now accurately known. Among the causes whose operation has been clearly traced, a prominent place is occupied by inoculable viruses which infect the system, such as syphilis, tuberculosis, leprosy—to mention only the more common. Ricord, Fournier, Sigmund, and Hutchinson have shown how many and various are the cutaneous manifestations of syphilis, and with what versatile mimicry it assumes the form of other diseases of the skin. Tuberculosis has been proved to be accountable not only for lupus, but for affections formerly classed under the heads of lichen and erythema and for the other forms of skin disease included under the general term scrofuloderma. The sorting out of the cutaneous affections due to these two causes alone has greatly reduced the region of the unknown in the map of dermatology.

The Action of Parasites.—Another direction in which the etiology of skin diseases has made decided progress is the recognition of the action of parasites. The idea that scabies is due to the irritation set up in the tissues by an animalcule, and ringworm by the growth of a vegetable mould on the surface of the skin, is so familiar to us that it is not easy to realize how recently the truth of these doctrines has been definitely established, and with what incredulity the discoveries were for a long time received. The sarcoptes scabiei had been seen by Avenzoar in the twelfth century, and later by Guy de Chauliac, Ambroise Paré, and others, and in the seventeenth century it was distinctly indicated by Bonomo and Cestoni as being the cause of itch. It was rediscovered more than once afterward, but it was not till 1834 that Renucci, in Alibert's clinic, was able to show how it could always be found.[8] Yet in 1850 Antony Todd Thomson is allowed to say, without a word of protest from his editor, Parkes, that itch is certainly "the result of a morbid poison, and that the fluid of the vesicles or the pustules is the agent transmitting the disease;" and while awarding Wilson credit for his accurate description of the acarus Thomson expresses his inability to "accord with him in attributing the disease to that insect."[9] Still later we find a dermatologist like Devergie writing: "The acarus is a morbid product of the itch as the mycoderm is the morbid product of ringworm, as the insect of acne punctata is the morbid product of that disease, as the louse is the morbid product of pediculous prurigo. Ringworm is contagious through the medium of this mycoderm, not only from child to child, but from the head of a child to the bark of certain trees, and the lousy evil[10] from person to person. Ringworm, acne punctata, and the lousy evil, do they originate the less spontaneously on that account? The means that we use to destroy the acarus, are they not also suitable for curing the erup-

tion of itch?" The fact that only forty years ago a dermatologist of the first rank could thus in one sweeping anathema condemn root and branch the doctrine of parasitism in skin diseases is one of the most striking proofs of the youthfulness of scientific dermatology, and of the progress which it has made in its lusty childhood.

The discovery of the vegetable fungi which cause ringworm, favus, tinea versicolor, and erythrasma, unlike that of the itch mite, was not made in the dark ages, but almost in the full glare of the light of modern science; yet it was received with equally resolute disbelief by some of the leaders in dermatological Israel. In 1839 Schoenlein discovered the fungus which produces favus; in 1844 Gruby in Paris, and Malmsen in Stockholm, almost simultaneously and quite independently discovered that which causes ringworm. Here, again, we find A. T. Thomson, in 1850, asserting in regard to favus that, though the disease has been ascribed to a mycoderm, "there is no proof of that opinion," and in regard to ringworm that "the pustules constitute the disease, and the mycoderm merely finds its habitat on them."[12] In the same year Cazenave[13] could scarcely bring himself to admit the existence of the achorion Schoenleinii, and, with regard to fungi in general in their relation to skin diseases, he was emphatic in warning investigators against "the illusions of microphotography," and denied that these "mysterious atoms" possessed any pathogenic property. In 1863 Chausit, a pupil of Cazenave, argued strongly against the cryptogamic origin of ringworm, concluding that "in the present state of dermatology there is no disease of essentially parasitic nature, and there is no such theory as antiparasitic therapeusis."[14]

Gibert, who had long been an obstinate recusant, gave in his adhesion to the parasitic doctrine in 1866, but Cazenave never recanted his heresy, and Erasmus Wilson, who, after Cazenave had passed away, stood alone in his refusal to accept the teachings of modern science on this subject, also died an unbeliever. The brilliant researches of M. Sabouraud have recently proved that the disease hitherto known as ringworm includes two, and possibly more, distinct conditions caused by different species of fungi. It has also been shown that the disease may be transmitted from animals—particularly the horse—to human beings, a fact obviously of the greatest practical importance. Sabouraud and other observers in other countries have thrown light on the geographical distribution of the ringworm fungus, and the remarkable fact has been brought to light that the species which causes the most rebellious form of the disease is most frequently met with in London, is unknown in Italy, and is very rare in Germany. This has an obvious bearing on the records of the results of treatment in those several countries. Another point which is suggested in recent investigations is that the boundary line between ringworm and favus is by no means so definite as has hitherto been believed. It is clear that there is yet much to be done in a subject which a short time ago was looked upon as worked out.

Bacteria and Skin Diseases.—During the last few years our ideas as to the action of parasites have undergone expansion. The influence of the great revolution in pathology brought about by the discoveries of Pasteur, Koch, and their disciples has been felt in the sphere of dermatology as in other departments of medicine, and we have learned to look for the causes of many diseases in the world of the infinitely little which bacteriology has revealed to us. Already lupus, leprosy, carbuncle, glanders, sycosis, furuncle, impetigo contagiosa have been proved to be the result of the mischievous activity of specific micro-organisms. It is practically certain that syphilis has a like origin, but the particular microbe responsible for its production is still "wanted" by our scientific police. More than one has been arrested on suspicion, others are being closely shadowed, and there is every hope that the actual criminal will soon be found. Eczema is considered by Unna, who has done much for the recent advance of dermatology, to be of microbic origin. A similar causation is assigned to psoriasis, and by others to alopecia areata, acne, and certain forms of erythema. Quite recently Sabouraud has brought forward evidence which he thinks sufficient to prove that seborrhœa and common baldness are of the bacterial family of diseases. These views are not yet accepted by all dermatologists, but there can be little doubt that as methods of research are perfected the "sphere of influence" of bacteriology in relation to skin diseases will become greatly enlarged. Already it extends far more widely than the brief list of diseases which have been definitely traced to microbic agency would seem to show. In almost every case of skin disease the primary and essential process is at some period of its course complicated, and it may be overshadowed by secondary lesions. To bacteriology we owe the knowledge that these are due to the action of pyococci and streptococci, whose attacks the skin resists in health, but to which it falls an easy prey when diseased. The importance of this knowledge, both in relation to diagnosis and to treatment, can hardly be overestimated.

Other Lines of Advance.—I can make only the briefest reference to other lines along which dermatology has advanced in recent years. Of these the most important has been the increased attention bestowed on the relations of various forms of cutaneous affections to disorders of the nervous system. In this field the most notable workers have been Bärensprung, Weir Mitchell, Morvan, Schwimmer, Radcliffe Crocker, and above all Leloir, whose untimely death was a grievous loss to dermatology. A large number of skin diseases presenting the greatest diversity in their objective features have been shown to be dependent on lesion or functional disorder of some part of the nervous system. Many diseases, such as zoster, erythema, pemphigus, scleroderma, and various forms of cutaneous œdema, hemorrhage, and ulceration which used to be called "idiopathic"—the medical equivalent for the "visitation of God" in the simple etiology of the British juryman—are now recognized to be consequences of vasomotor or trophic disturbance. We also know that defective innervation plays a considerable part as a predisposing cause, making the skin less able to resist harmful influences of any kind—injury, cold, heat, and irritants whether chemical or parasitic. In this way nervous disorder comes into play as a definite factor in many cases of eczema, lichen, and other affections. The late Mr. John Marshall threw out the pregnant idea that cancer might be an "anarchy of cells" due to loss of control by the nervous system. The same cause might account for some diseases of the skin. The neuropathology of the skin is a field that will well repay further cultivation.

Another line along which we have advanced is the establishment of a definite relation between certain constitutional states and affections of the integument. The tendency of the French school to look to the general system for an explanation of every blotch and pimple led them away from the truth no doubt, even to the invention of a diathesis when one was wanted: but some dermatologists have perhaps now gone a little too far in the opposite direction. It is well that with the all-conquering bacillus on every side extending the boundaries of his empire, we should not forget that other agencies have still to be taken into account. Gout has not the far-reaching influence in the production of cutaneous affections that it used to be credited with: but it is sometimes a factor that must be reckoned with. The connection of certain

forms of pruritus and herpes, of boils and carbuncles, of a particular variety of xanthoma with glycosuria is well known.

The influence of auto-intoxication requires to be more thoroughly studied than it has yet been; the effects of ptomains should also be fully investigated. The serum treatment which is now being tried in diphtheria and other diseases is making us familiar with toxin rashes; is it not possible that the prolonged operation of some similar cause might explain the origin of some skin diseases?

Progress in Power. — Bacon's aphorism that "knowledge is power" unfortunately does not always hold good in medicine. Yet we may fairly congratulate ourselves on a very decided gain in our power of dealing with skin diseases, especially in the last fifteen years. Progress has been made in three ways: (1) We have got rid of some superstitions; (2) we know better where to direct our attack, and (3) we have more effective weapons.

Among the superstitions that hindered progress one of the most pernicious was the notion that skin disease was a natural issue for the escape of peccant humors—a safety valve for the constitution. Hence in many forms of skin affection, and particularly in the case of eczema, it was believed to be dangerous to cure the cutaneous lesions, because the disease was thus "driven in" upon the internal organs. As a quaint illustration of this belief the following passage from our earliest English dermatologist, Daniel Turner, is interesting. Speaking of "Children's Scabs or Breakings-out," he quotes with implied approval the following admonition from "the most excellent Hildanus":

"Let Mothers have a Care how they set about the Cure of this Malady, unless it be so virulent as to hazard corrupting the Parts it lies upon. My eldest Son [says he] till he was seven Years old had not a Speck upon his Body, wherefore I often foretold that some sudden and mortal Disease would seize him; and, indeed, being taken with a Stoppage of Urine, he died the seventh Day of the Disease of a great Inflammations of the Kidnies and Parts adjoining which turned to a Gangrene: Nature, to-wit, not being able to purge the Body of vitious Humours by the Itch, they in the seventh Year, as by a critical Expulsion, fell suddenly from other Parts upon the Loins. In my Practice I have met with several Diseases both internal and external in young Children in whom these Breakings out were either not naturally expell'd or violently dry'd up. Therefore, let the honest Physician abstain from Medicines; and if there be a Necessity, let the pain of this Itch in Children be only mitigated with Fresh Butter or with the same washed in Rosewater."[15]

Willan and the other dermatologists had the fear of "repelling" diseases of the skin ever before them. Perhaps the most grotesque instance of superstition is a case referred to by Duhring as being recorded by a Boston doctor. This enlightened practitioner, finding two African children afflicted with body lice, put them into a warm bath; on being suddenly freed by this means from their vermin, they incontinently "dropped down and expired immediately." But the fear of "driving in" skin disease is not yet by any means extinct in the medical profession or even among dermatologists; it would be easy to quote passages in proof of this from living writers of authority.

Increased precision in the direction of attack naturally arises from increase of knowledge as to the nature, and especially as to the causation, of cutaneous affections. Nowadays we at least do not, as Archbishop Whately said of the common run of preachers, "aim at nothing and hit it." The polypharmacy in which the older school of dermatologists delighted is almost a thing of the past, and patients are not plastered in the wholesale and indiscriminate manner that used to be thought necessary for the correction of their constitutional depravity. Internal medication is used only in response to definite indications, and we work the "miracle of cure," to use a too celebrated phrase, with the help of a simpler, pleasanter, and more efficient pharmacy. The improvement in our weapons lies mainly in the methods of preparing and employing the old remedies, but newer ones are not wanting.

The administration of remedies by hypodermic injection may be mentioned as one of the most promising improvements in constitutional therapeusis; the use of mercury in this way in syphilis is becoming more and more common. The serum treatment has not yet established itself in dermatological practice, but good results from it have been reported in a few cases of syphilis, lupus, leprosy, and one or two other affections. Tuberculin as first prepared by Koch has in my own hands and in those of some other observers proved of distinct use as a preliminary to surgical treatment in lupus. The newer tuberculin lately "placed on the market"—I am sorry to have to use this commercial phrase, but it accurately expresses the fact—gives promise of much greater usefulness, but it is too soon yet to pronounce a definitive judgment as to its real efficacy. Thyroid extract has a powerful immediate effect on the integument, but my own experience does not lead me to attach much value to it as a remedy in skin disease, and that opinion is confirmed by the experience of several other dermatologists.

But it is in our means of local treatment that the improvement of our weapons is most marked. The application of the parasitic doctrine to skin diseases has led to the introduction of a large and constantly increasing number of parasiticides—powerful agents that the midcentury dermatologists knew not of. Then both the preparations and the methods of applying them are cleanlier and more effective. The pastes, plaster mulls, varnishes, soaps, sticks, and other devices for the application of remedies which we owe to the ingenuity of Pick, Unna, Lassar, Brooke, and others have revolutionized the local treatment of skin disease. Our surgical methods and appliances, our antiseptics, our cauteries, and so forth, are also immensely superior to those in use twenty years ago.

Do we cure more than our scientific forefathers did? I think we may unhesitatingly answer, "Yes." Parasitic diseases are certainly more under our control, and in nearly every form of skin disease we can treat symptoms more effectively, and give relief even when we fail to cure. We are altogether milder in our methods than the dermatologists of a former day; we soothe instead of irritating; we strengthen instead of depleting; we leave nature to herself instead of thwarting and teasing her into active rebellion. But there is still a good deal of overtreatment, and I not infrequently see patients whose disease has been aggravated into frenzy, so to speak, by the continuous goading of injudicious treatment. The policy of "masterly inactivity" finds a large sphere of application in dermatology.

The Future of Dermatology.—I have given a review of the past, very hasty and imperfect, but I can only, like swift Camilla, skim across the plain. I may be allowed to conclude with a peep into the future. Whether the newer medication with serums and organic extracts holds in it much promise for the treatment of skin disease it is of course impossible to say; I am, however, inclined to think that in this direction, and in that of increase of power of dealing with parasitic affections, lies the path of development in dermatological therapeutics likely to lead to the best results. It will be long before a complete classifications of diseases of the skin is possible, but this is of no great practical importance. A real stumbling-block,

however, is the confusion of terminology that still exists. It would be a very real help to progress if a nomenclature at once simple, precise, and yet descriptive and international could be devised.

SOME PRACTICAL OBSERVATIONS ON PULMONARY TUBERCULOSIS.

By HUBBARD WINSLOW MITCHELL, M.D.,

MEMBER, NEW YORK ACADEMY OF MEDICINE, MEDICAL SOCIETY OF THE COUNTY OF NEW YORK, NEW YORK COUNTY MEDICAL ASSOCIATION, PHYSICIANS' MUTUAL AID ASSOCIATION; EX-PRESIDENT, MEDICAL SOCIETY; EX-VISITING SURGEON, BELLEVUE HOSPITAL, OUT-DOOR DEPARTMENT.

Pulmonary tuberculosis is a disease which occurs perhaps more frequently than any to which mankind is subject, appearing in persons of all ages, in every clime, and under all conditions of life.

It is now accepted as a fact that this disease is due to the introduction into the lungs of a micro-organism known as the tubercle bacillus. This tubercle bacillus is a short, delicate rod, slightly curved, and having a length of from one-half to one diameter of a red blood globule. When stained with a solution of carbolic fuchsin it assumes a bright red color, and under the microscope presents a well-defined body with from two to five vacuoles. These vacuoles give it a sort of beaded appearance, and it is probable that they are the nuclei of new bacilli, which are formed by the fission and subdivision of the parent bacillus. It is doubtless true that these bacilli multiply by a rapid subdivision of themselves. When the bacillus is thus stained with carbolic fuchsin it slowly assumes a bright red color, which is permanent after treatment with strong acids, and this characterizes it from all other known forms of bacteria. It can be cultivated in various media, such as blood serum and potato, when the cultures are kept at blood heat. They grow slowly and appear at about the end of two weeks, forming colonies of bacilli in grayish-white masses on the surface of the culture medium. But little is yet known of the chemical composition of these little organisms. They multiply with great rapidity in lung tissue, and a patient suffering with pulmonary consumption discharges them in the sputum in considerable numbers. It is an exaggeration to state that they are discharged by millions by every patient daily in his sputum. They do not occur in any such vast numbers. They are plentiful, it is true, but not by millions. They are extremely tenacious of life, and retain power to do harm even when dried for a considerable length of time. When they are expectorated in the sputum of a patient, great care must be taken to destroy their virulence, else they become a focus of danger to others wherever they are discharged. The sputum of phthisis is a dangerous substance unless it is most carefully disposed of or rendered sterile.

In the dust collected from the walls and bedsteads of hospital wards, in prisons and asylums where phthisis patients have been kept, bacilli have been found in considerable numbers, showing that in these places the sputum was not properly rendered sterile and harmless, and new foci of infection were thus formed.

Mode of Infection.—It is doubtful if phthisis is hereditary. Hitherto life-insurance companies have rejected applicants for insurance whose parents or members of the family have died of phthisis, even when the applicant himself was in perfect health. It is a disputed point how far the theory of heredity is true, but from my own observations and studies I do not believe that the ancestors of such persons conferred a taint sufficient to warrant his rejection.

If a woman afflicted with phthisis becomes pregnant (and this is a common occurrence), it is very doubtful if she can transmit it to her child. If a man suffering with phthisis impregnates a woman, the venereal act does not transmit the disease to her or her child. The semen, so far as known, contains no bacilli. Heredity, therefore, is of little value to-day.

The following is a case in point:

Mrs. A——, aged twenty-nine, came to me on April 1, 1894, suffering with phthisis. She was pale, anæmic, extremely emaciated, had night sweats, and no appetite. She had had several hemorrhages from her lungs during the preceding six months; her right lung, upper lobe, was infiltrated with purulent matter, with coarse bubbling râles; her cough was distressing, her sputum copious and contained pus cells and bacilli. She was eight months advanced in pregnancy. She could give no definite account as to when she first began to cough.

April 30th she was delivered of a healthy female child at full term.

On June 1st I began to give her treatment relating especially to her lung disease. This was continued steadily until December of that year, when she left me, at which time her sputum contained no bacilli and all her symptoms were greatly relieved.

July 1, 1895, she gave birth to a boy at full term and perfectly healthy.

September, 1896, she gave birth to a third child, a boy, at full term, also perfectly healthy. She began to cough when the child was two weeks old, and applied to me for treatment. With the exception of a slight bronchitis she was well, and remained so till this date. Her three children are living and have shown no signs whatever of receiving any taint from their mother. The father is a perfectly healthy man.

The mode of infection, then, is by inhaling a germ from some outward source, and doubtless in this way only.

Contagiousness of Phthisis.—Accepting as we do the theory that phthisis pulmonalis is a result of the introduction into the lung of the tubercle bacillus, then that microbe must surely be introduced from without and from some source where the bacillus has retained its activity and its virulence. Remembering that the sputum from phthisis patients contains considerable numbers of these bacilli, which are distributed widely

through dust and the careless voiding of sputum, it will be seen that the danger from this source is very evident and the acquirement of the disease in this way is very certain.

Kissing a phthisis patient is a source of danger, from the fact that bacilli may be present upon the lips or in the buccal cavity of such a patient, and the person thus kissed may introduce into his own air passages one of these dangerous microbes and thus acquire the disease.

But contagion from personal contact at home, in hotels, or sanatoriums, or from inhaling the breath of a phthisis patient is a very doubtful source of danger, and is not believed in by the majority of experienced and competent physicians.

Cases have been recorded (with more or less truth) in which phthisis has been acquired by inoculation, as from persons washing the clothes of such patients, or the bite of a tuberculous person, or inoculation from a cut or abrasion where the sputum has been dried in contact with an open wound. Further light on this point is needed.

The common house fly (Musca domestica), feeding upon sputum containing bacilli, has been found to contain these microbes in his body, and has thus perhaps disseminated them more or less widely. Several observers have found bacilli in the bodies and upon the surface of these flies. This insect may possibly be a means of spreading the disease, as well also as some other members of the order Muscariæ.

Influence of Age.—Tuberculosis occurs in all periods of life. The nursing babe is its victim, and the innocent child, as well as are those whose sands of life are nearly run. No age is immune to this dread disease. In young persons we find the lymphatic glands frequently and often extensively affected. In the middle-aged and the old, the lungs seem to be especially prone to this disease.

Locality and Soil.—My personal experience and observations lead me to say that locality and soil play an unimportant part. It has been the custom and the fashion hitherto to send patients away from their homes in our Eastern cities to higher altitudes, in the belief that an elevation of from three thousand to eight thousand feet above sea level is beneficial to tuberculous diseases of the lungs. We thus get rid of the patient, but not the disease, and in too many cases he comes home to die, or dies before he can get home. The relief he obtains in being sent away from home is very doubtful.

I have spent considerable time in travelling in the Catskills, Adirondacks, and the Rocky Mountains, investigating with some care these localities, with their varying altitudes above sea level and their influence upon the lungs, and, while perhaps a high and dry and lighter air may be beneficial in some diseases and for its influence upon the general health, I do not believe that it has the slightest effect upon the growth and proliferation of the tubercle bacillus itself. In this opinion I am heartily confirmed by the judgment of many able and careful practitioners with whom I have most earnestly conversed, and I repeat that altitude has no influence whatever in destroying the tubercle bacillus. A considerable experience with this disease has led me to believe that no place is better for its treatment than New York City. Patients have come to me from every State in the Union, from Canada, from the Sandwich Islands, and from Europe; and it appears to be the general belief among them all that the climate of New York City, with its clear air and bright sunshine, is quite as favorable under all circumstances as is that of most other localities. I have under my care at this time patients from several towns in Colorado, from New Mexico, and California, and all are doing better in this city than in their own localities.

Action of Bacilli.—It is interesting to note the changes which occur in the pulmonary tissue when a bacillus has been successfully introduced. When a bacillus so enters the lung tissue it is followed almost immediately by an inflammatory action of the spongy tissue of the lung and the formation of small rounded masses, which are termed "tubercle." When these tubercle masses are once formed they quickly undergo a process called caseation. This caseation is a process of coagulation going on in the lung cells; they lose their outline, become irregular, and are converted finally into a structureless substance, and are gradually converted into a yellowish-gray pus, in which the bacilli are more or less abundant; and when this matter infiltrates the inflamed lung tissue it is loosened more or less by the inspired air, escapes first into the smaller bronchi, then into the larger, and is finally coughed up by the patient in the form of a thick, yellowish, grayish, or greenish sputum, containing bacilli more or less abundantly.

This sputum is the medium of contagion, and must be rendered sterile if we would prevent the extension of the disease to new and helpless and innocent victims.

Temperament.—Temperament seems to play an important part in the acquirement and behavior of phthisis. Persons who are tall and thin and anæmic, and those with red or sandy or light hair, and thin, pallid skin and pale mucous membranes, and weak sexual organs, seem to be very liable to tuberculous disease; those having the alkaline temperament far more so than do the shorter, darker-hued, and more athletic persons, or those of the acid temperament, according to Dr. Gibier.

In this class of cases, the alkaline, it would seem that the apices of the lungs and the subscapular regions are the favorite localities where this disease loves to burrow. It is here that cavities form more readily, and the disease seems more persistent than when in the middle or lower lobes. When the patient who is tall and pale and badly nourished, whose blood is anæmic, acquires phthisis, one or the other apex is very often involved, and he resists treatment to a great degree. In this class of cases also, and when the disease has made any headway, the poisonous principle of the disease, whatever it may be (ptomains or what not), seems to pervade the entire body, and we have in consequence diarrhœa, night sweats, hemorrhages, loss of appetite, and an inability to assimilate the little food taken. These patients seem to fall before this disease as readily as grass before the mower's scythe. In this class of cases phthisis is so difficult and persistent that it appears almost malignant.

Not all persons who inhale tubercle bacilli contract the disease. Were it so, few persons would escape; but in order that this bacillus may gain a lodgment in the lung, a lowering of the vitality must be present, and the lung tissue must be weakened from some cause. When such a weak lung or special temperament or adaptability to receive the disease is found, it becomes a ready prey to the immigrating microbe. In probably the majority of cases in which bacilli are introduced into the lung tissue, they are for some reason destroyed at once and do no harm, and this reason is either an acid temperament or a power to resist disease; but in other cases, in which I have said the lung for some reason forms a congenial habitat, the bacilli grow luxuriantly, caseation and softening occur, and the invading army of bacilli gains a victory which ends in death, unless checked at the outset by appropriate treatment.

Tuberculosis in the Lower Animals.—In the animal kingdom we find certain species that contract pulmonary tuberculosis more or less readily. Animals who thus acquire the disease are those which come in

contact with man, either in the feral or the domestic state. Among the feral group comes first the order of apes.

Apes may be divided into two general classes, as follows: The Cynomorpha or dog apes; the Anthropomorpha or man-like apes. All of these have been called catarrhine apes; that is, having a nose somewhat narrow, with a thin septum.

Some years ago, while I was visiting West Africa, I spent some time on the Congo River, and in the wild and unknown regions bordering the south bank of that great stream I saw considerable numbers of baboons. Of these, the anubis baboon (Cynocephalus anubis) was the most common and numerous. They are a very wary, alert, and mischievous animal, living in troops of twenty or more, and love to approach the dwelling of man, where their thievish propensities cause them to be regarded by the natives as a great nuisance.

The mandril (Cynocephalus mormon) and the magot (Macacus sylvanus) are also frequently met with on both banks of the Congo. I have seen them in considerable numbers, and their curiosity has led them to approach us very closely. On several occasions, while we were hunting for deer and other game, a group of baboons would be seen hovering over one of their number who appeared to be unable to move. It was easy to approach him, as he was too feeble to escape. His companions scampered away and watched me at a short distance, with amusing curiosity. Inquiring of the natives what the trouble was, I found that the baboons were frequently taken ill with some chest trouble which was similar to that from which the natives themselves suffered. This I learned afterward was phthisis, which is not uncommon among the blacks in the lower Congo district.

In the wild and almost uninhabited country about one hundred and fifty miles north of Cape Town in South Africa, the common baboon is very numerous and a most unwelcome visitor to the negroes, who suffer severely from his thievish and predatory acts. On several occasions during the twilight, and at a distance in the daytime, I have mistaken these animals for small negroes, as they frequently sit upright and sometimes walk on their posterior limbs aided by their arms. This was the common baboon (Cynocephalus papio). They are found in this locality in considerable numbers, and have very little fear of man. An English officer who lived at this point, whom I visited, told me that the natives frequently contracted phthisis on their visits to Cape Town, and it seemed probable that the sputum of these people, being carelessly voided in their gardens and about their houses, was communicated to the baboons in some of their marauding expeditions, and this gentleman told me it was not an uncommon sight to see a sick baboon presenting the same symptoms as the natives when suffering from phthisis.

I soon had an opportunity to verify this fact. One day, while hunting in the adjacent hills, I came across a baboon lying on the ground, who was extremely emaciated and had a severe and violent cough. At that time the existence of the tubercle bacillus was not known, but I felt sure that the animal was suffering from pulmonary tuberculosis.

The Domestic Group.—The common ox (Bos taurus) is frequently afflicted with pulmonary tuberculosis; so much so, in fact, as to make necessary a rigid surveillance of our great abattoirs by competent and authorized inspectors. Undoubtedly these animals contract the disease from their long and close proximity to the genus Homo.

The dog (Canis familiaris) and the cat (Felix domestica) are both extremely liable to pulmonary tuberculosis, and this would seem almost a foregone fact from their intimate association with man.

The duck (Anas boschas), the goose (Anser anser), and the domestic fowl rarely but occasionally contract this disease. It is not improbable that other animals fall victims to tuberculosis, but they do not specially interest us here. It is those animals with which we deal daily, and whose flesh and milk we consume as articles of food, that interest us most closely.

Symptoms.—The train of symptoms of pulmonary phthisis are well known, and I need not dwell upon them here.

Diagnosis.—The diagnosis of pulmonary phthisis is in most cases very plain. The presence of cough, expectoration, emaciation, night sweats, diarrhœa, anorexia and thirst, loss of flesh and general anæmia, with hemorrhages more or less severe, are almost always met with, and point to the true nature of the disease. But the unfailing test in diagnosis is the presence of the bacillus in the sputum. If it contains no bacilli then the disease is not pulmonary tuberculosis *per se*. A very early diagnosis can thus be made.

The experienced and careful physician has very little difficulty in making a correct diagnosis, even without the immediate examination of the sputum. He may prescribe at once for a case, but he must very soon after examine for bacilli, in order to confirm his judgment, and frequently during treatment, that he may know if they are diminishing (if present) and whether his patient is really recovering or not.

Prognosis.—Pulmonary phthisis, when not modified by treatment, is an extremely fatal disease. No accurate percentage of deaths can be given, because these percentages differ with many writers, but when the disease is allowed to run its course without treatment it is a rapidly and terribly fatal malady.

The Economic Value of Disease. — Some writers hold that disease, and especially tuberculosis, has a certain economic value in preventing the overpopulousness of the earth. In past geological ages, the exuberance and overpopulousness of animal life on the earth has been regulated and held in check by the operation of several influences. The lower forms of life that have been so prolific in their reproduction have been preyed upon by the higher orders of animals, which used them as food. Every species of animal has found a destructive enemy in some other species of animal, and this process of one animal preying upon another has served in all ages as an effectual check upon the overproduction of any one species.

With man there was no other or higher animal to hold in check the rate of his increase. To regulate and repress his too exuberant reproduction three influences quickly sprang into activity. They were: first, his internal destructive warfare; second, the ravages of disease; third, his own individual vices.

His early tribal quarrels continued until supplanted by more destructive modern warfare, and these influences acted with such baleful force as on several occasions seriously to affect the welfare of mankind. Thus in the reign of the Roman Emperor Justinian, A.D. 527–565, the influences of his wars, with the famine and disease that followed, destroyed one hundred million of human lives and caused a visible diminution of the human race.

The ravages of disease have acted as a powerful check upon the increase of mankind. As people aggregated into communities and nations, and lived in close contiguity, they were ignorant of sanitary laws, and they suffered severely from sporadic and epidemic disease. Tuberculosis played a malignant and destructive part, and it is said destroyed one-third of all those who died of disease. Whether this special disease has any economic value or not, we can hardly say; but while the question is being argued by the theorist, the practical physician will do all in his power to abate its terrors.

The individual vices of men have certainly some economic value. The habitual criminal, the cruel and morbidly vicious, the drunkard with his ungovernable craving for intoxicants, and the prostitute, are all victims of disease and lack the mental balance necessary to make them sound and responsible beings. It is from the ranks of these classes that the insane are largely recruited. If they allow unrestrained action to their vicious or intemperate habits, the prison, the hospital, or the grave ends their career.

Treatment.—At the outset we must distinctly remember that pulmonary tuberculosis is an inflammatory disease of the spongy tissue of the lung, due to the introduction of a special microbe, and followed by a true ulcerative and suppurative process in the lung substance. This may, then, be described in a word as a special ulceration of lung tissue with an expectoration of the suppurating matter, and any treatment which is destined to cure or even relieve it must be addressed to the actively ulcerating condition of the lung.

Many remedies have been advocated for the treatment of this disease, and at the present time both the lay and medical journals are teeming with the discovery of this or that person who has a "consumption cure." In many cases doubtless this activity is due to an earnest desire on the part of the discoverer to find something which will modify or cure tuberculosis. Whether serum or subcutaneous injections of any special remedy, or whether medicated inhalation will be of lasting benefit, is a problem yet to be solved. When we remember that phthisis is an active ulcerative process of the lungs, it would seem that these lines of treatment are not adapted to its cure.

It would also seem that some remedy which can be introduced into the body at short intervals and for a long period of time, something that will act as an antiseptic by saturating the blood and so modifying or destroying the bacillus, and at the same time inflict no injury upon the other organs of the patient, must be the ideal remedy.

If, as has been stated above, a considerable proportion of cases of phthisis belong to the alkaline temperament, then a remedy of an acid reaction would appear to be especially indicated.

My own experience, which has been large, leads me to believe that a solution of the halogen group of salts with the hypochlorite of sodium is the best remedy with which I am acquainted, to modify and perhaps cure pulmonary tuberculosis. This remedy acidifies the blood when saturated with it, and almost immediately relieves the extreme anæmia, loss of appetite and of strength, and night sweats, which form such distressing symptoms. The cough, which is almost always present and sometimes distressing and even terrible, can easily be relieved by giving a mixture of iodide of potassium with a little sulphate of morphine and a syrup as a vehicle. An elegant preparation can be made by properly combining these drugs.

For the hectic fever, nothing is better than a capsule containing four grains of sulphate of quinine and one-fiftieth of a grain of sulphate of strychnine, once or twice daily. Whiskey and brandy may be given when indicated, but never wines or malt liquors.

Diet should receive especial attention, and nutritive and easily assimilated articles of food should be selected and the patient particularly instructed in their use. Rest should be enjoined as complete as the case will permit. Nature has given us a powerful aid in balmy sleep.

It is not necessary in my judgment to isolate cases of consumption, for, as far as I have seen, patients suffering with this complaint are quite amenable to reason, and will, if properly instructed, exercise care and caution in the matter of sputum and excreta from themselves. All of the patients whom I have treated have gone to their own homes, and, as far as I have been able to discover, none of them has communicated the disease to those immediately about him, and the treatment has continued over a considerable period of time.

The ideal treatment of pulmonary phthisis would be the above carried out in a hospital or sanatorium especially erected for this line of work. Such a hospital should be built in a manner which will make antisepsis practical in every way. The rooms should be small, finished in hard or painted wood, with hard-finished ceilings and walls, and hardwood floors. Iron bedsteads, a washbowl containing hot and cold running water, and a small bureau and chairs would complete the furniture equipment. The rooms should be lighted by electricity and heated by steam, so that an equable temperature could be maintained throughout the year. A solarium should be provided in the upper part, with white and colored glass, where patients in bad weather can sit, and sheltered walks should be provided where proper exercise can be had. Whatever treatment is adopted must be persisted in faithfully and thoroughly by both patient and physician, and for long periods of time; and with such an equipped place and honest treatment I believe that a considerable percentage of cases of phthisis can be cured and many others greatly relieved.

747 Madison Avenue.

MENTAL EVOLUTION IN MAN.[1]

By R. M. Bucke, M.D.,

Medical Superintendent of the Insane Asylum, London, Ontario, Canada.

About sixty years ago now, in the time of the Millerite excitement, a man who believed that the world was about to end expressed his fears to Emerson, who replied that it was really a matter of little consequence, "for," said he, "we can do very well without it." There are wise men who teach that each man creates the world he lives in, and as he gives it its substance so also does he give it its quality, insomuch that it is good or bad as he is good or bad. Be this as it may, it is certain that each one of us is of more consequence to himself than is all the outside world, be it shadowy or be it solid; be it created by each inhabitant or be it independent and self-existent. Not only so, but the essential part of each man is what we call his mind, in comparison to which the body is an insignificant factor.

The Study of Psychology.—This being granted, it would seem to follow that psychology ought to be the most interesting of all the sciences, and as a matter of fact it undoubtedly is so, though it has been greatly discredited by the imperfection of the method by which it has until very lately been studied. That imperfection is so great that it would hardly be an exaggeration to assert that nearly all the study and thought expended upon it down to the beginning of our own age has been fruitless and as good as wasted, except inasmuch as it has at last made clear the impassability of the route men have sought to follow, the route, namely, of introspection. For we might as well study the human body alone without reference to that of any other creature, and attempt in that way to decipher its genesis, development, and meaning, as to attempt to comprehend a single human mind without including in our examination not only other human

[1] An address delivered at the opening of the section of psychology, at the annual meeting of the British Medical Association at Montreal, September 1, 1897.

minds in all stages of evolution, but equally all other minds to which our own is related—that is to say, all minds other than human belonging to our kinsfolk the animals, minds which stand to-day like mileposts along the almost infinite length of the path which our mind has followed in its upward march across the immensities and eternities from its remote infancy to the present hour; minds which in a thousand faculties represent to us everywhere, in infinite sameness and variety, replicas of our own or of parts of our own, showing us, as the poet says, tokens of ourselves which we "negligently dropped as we passed that way huge times ago."

Comparative Psychology.—As man's bodily life rests upon and grows from that of countless prehuman ancestors; as man includes in his structure the heart of the reptile, the gills of the fish, as well as the forms in outline of innumerable still lower races, so is his so-called human mind rooted in the senses and instincts of all his ancestral species; and not only so, but these senses and instincts still live in him, making up, indeed, far the larger part of his current every-day life; while his higher psychical life is merely the outgrowth and flower of them.

As truly as the plant is an embodiment of inorganic matter vivified by the transmuted forces which in the non-vital world about us we call light and heat, so truly is man's mind the outcome of—the expansion and culmination of—the imperfect sensation of the worm, the rudimentary sight, hearing, and taste of the fish and reptile; and the simple consciousness which, springing from these, passed to us after almost infinite ages of slow evolution and amelioration through tens of thousands of generations of placental mammals our immediate progenitors.

In the growth of mind, whether that of the race or of an individual, we recognize two distinct processes: First, the very gradual evolution to, or toward, perfection of faculties that have already come into existence; and, secondly, the springing into existence (as new branches start from a growing tree) of faculties which had previously no existence. For it is clear to the least thoughtful student that no faculty (as no organ) came into mature and perfect life at once. Hearing and sight, we are told, developed by slow degrees from the sense of touch; and in the region of the intellect conceptual life was born from ages of receptual, and that from millenniums of perceptual.

Mental Growth in the Individual and in the Race.—Let us now suppose mind growing for millions of years in the way set forth. It begins, we will say, as mere excitability; to that after a long time is added what may be called discrimination, or choice and rejection of, for instance, different kinds of food. After another long interval of almost infinitely slow advance sensation appears, and with it the capacity of pleasure and of pain; then, later still, memory; by and by recognition of offspring; and successively thereafter arise reason, recognition of individuals, and communication of ideas. Concurrently with these intellectual faculties certain moral functions such as fear, surprise, jealousy, anger, affection, play, sympathy, emulation, pride, resentment, grief, hate, revenge, shame, remorse, and a sense of the ludicrous have also arisen in the nascent mind. We have reached now the mental plane of the higher animals, which is equally that of the human being at about two years of age. Then occurs in the child the mental expansion which separates man from the higher mammals—for something like a year the child mind steadily grows from the status of the latter to the status of the human mind. This year in the individual, during which it walks erect, but possesses a receptual intelligence only, not having yet the power of forming either concepts or true words, represents in the race the age of the *alalus homo*, the period of perhaps a hundred thousand years, during which our ancestors walked erect, but, not having self-consciousness, had no true language. At the average age of three years in the individual self-consciousness is born, and the infant, from the point of view of psychology, has become a human being. But we all know that after the attainment of the distinctively human faculty, self-consciousness, the child has still much to acquire, both in the way of the expansion of already possessed faculties and in the acquisition of new ones, before it is mentally a mature man. Of the numerous faculties which it still has to acquire I shall mention only here the color sense, the sense of fragrance, the human moral nature, and the musical sense. A consideration of these four and of self-consciousness will occupy the short time allotted me to-day.

And first a word as to that basic and master human faculty, self-consciousness. It occurs, as said, at about the average age of three years, but when it first made its appearance in the race it must have done so at full maturity; perhaps at the age of twenty, both life and childhood being shorter at that time than they are to-day. You will see at once why I say self-consciousness must have occurred at first at maturity. Its acquisition at a given epoch supposed a higher mental life than had hitherto existed—such higher life on the part of the race could not have come to the individual before his maturity. To suppose that it would be (if you will think of it) a contradiction in terms. The human mind attains it high-water mark at maturity (that is what the word means), and one generation could not reach before maturity what the preceding generation had not reached at all. Well, but self-consciousness occurs to-day at three years of age, and we reach full mental maturity (on the average) only at the age of thirty-five. The advance then made by the individual from the age of three to that of thirty-five represents the advance of the race between the date of the appearance of self-consciousness and to-day, the mental status of the three-year-old child to-day being the mental status of the adult when self-consciousness first appeared. How long has it taken the human mind to grow from mere self-consciousness to its present stature? Not less certainly than several hundred thousand years. Whatever the time required is the time during which man has inhabited the earth.

Of all the mental faculties below self-consciousness each one has its own time for appearing in the human infant—as, for instance, memory and simple consciousness appear within a few days after birth, curiosity ten weeks after, use of tools twelve months after, shame, remorse, and a sense of the ludicrous—all of them about fifteen months after birth. Now it is to be noted that in every instance the time of the appearance of a faculty in the infant corresponds with the stage at which the same faculty appears (as far as can be at present ascertained) in the ascending animal scale; for instance, memory and simple consciousness occur in animals as primitive as the echinodermata, while the use of tools is not met with below monkeys, and shame, remorse, and a sense of the ludicrous are almost, if not entirely, confined (among animals) to the anthropoid ape and the dog.

To turn now to the true subject of this paper, I want to say in the first place that as in prehuman so in human psychology each superadded faculty was acquired in its own time in the history of the race, and that that historic period corresponds with the time in the life of the individual into whom the faculty is born to-day. For instance, self-consciousness appears in the individual at the age of about three years—it appeared in the race several hundred thousand years ago. It has been proved by Geiger and others that our color

sense has been acquired by the race not more than about thirty thousand years ago. Well, it is acquired by the individual at the age of about five or six. It is thought that the sense of fragrance was acquired by the race later than the color sense; it is also acquired later by the individual. Some considerable study of history has led me to the conclusion that our human moral nature cannot be more than ten thousand years old. For a careful consideration of the records that have come down to us from the early Romans, Hellenes, Hebrews, Egyptians, Assyrians, and Babylonians, would indicate, I think unmistakably, that, as we go back into the past, this faculty tapers down toward the vanishing-point, and that if it continues so to taper as we ascend the ages all of what we distinctively call our human moral nature would certainly have disappeared by the time we had gone back the number of centuries mentioned—that is ten thousand years.

Well, to-day the human moral nature in the individual, instead of being born at the age of three years as is self-consciousness, or at five or six as is the color sense, does not come into existence before the average age of about fifteen years. As to the musical sense, it is almost certainly less than five thousand years old in the race, and, when it occurs at all, is not usually born in the individual before adolescence.

There are three other laws, each well worthy of notice, which govern the acquisition of new faculties by any given race. They are as follows:

1. The longer a race has been in possession of a given faculty, the more universal will that faculty be in the race. This proposition scarcely needs proof—every new faculty must occur first of all in one individual, and as other individuals attain to the status of that one they too will acquire it, until after perhaps many thousands of years, the whole race having attained to that status, the faculty shall become universal.

2. The longer a race has been in possession of a given faculty, the more firmly is that faculty fixed in each individual of the race who possesses it. In other words: the more recent is any given faculty, the more easily is it lost. High authority, such as that of Charles Darwin, could be quoted in support of this proposition; but it scarcely seems to be required; it is almost, if not quite, a self-evident proposition.

3. A study of dreaming seems to reveal the fact that in sleep such mind as we have differs from our waking mind, especially by being more primitive; that, in fact, it would be almost strictly true to say that in dreams we pass backward into a prehuman mental life; that the intellectual faculties which we possess in dreams are, especially, recepts as distinguished from our waking concepts; while in the moral realm they are those faculties such as remorse, shame, surprise, along with the older and more basic sense functions, which belonged to us before we reached the human plane; and that the more modern mental faculties, such as color sense, musical sense, self-consciousness, the human moral nature, have no existence in this condition, or if any of them do occur it is only as a rare exception.

Let us now compare, one with the other, a few of the faculties which have been already mentioned in the light of the rules laid down. To do this will give us, more clearly than perhaps anything else could, a definite notion of the growth of mind by the successive addition of new functions. For this purpose we will take simple consciousness, shame, self-consciousness, color sense, the human moral nature, and the musical sense.

Simple Consciousness.—Simple consciousness makes its appearance in the human infant at the age of a few days; it is absolutely universal in the human race; it dates back certainly to the earliest mammals, and probably much earlier; it is lost only in deep sleep and coma; it is present in all dreams.

Shame.—Shame is said to be born in the human infant at the age of fifteen months; it is a prehuman faculty, being found in the dog and in apes, and undoubtedly existed in our prehuman ancestry; it is almost universal in the race, being absent only in the lowest idiots; it is very common in dreams.

Self-Consciousness.—Self-consciousness makes its appearance in the child at the average age of three years; it is not present in any species but the human; it is, in fact, that faculty the possession of which by an individual constitutes him a man. It is not universal in our race, being absent in all true idiots; that is, it is permanently absent in about one in each thousand human beings born into the world. In our ancestry it dates back to the first true man; a race, we are told, unclothed, walking erect, gregarious, without a true language, to a limited extent tool using, destitute of marriage, government, or of any institution, animal, but in virtue of its highly developed receptual intelligence king of animals, which developed self-consciousness, and by that fact became man. It is impossible to say how long ago it was when this event occurred, but it could not have been less than several hundred thousand years. This faculty is lost much more easily and frequently than is simple consciousness. We lose it in coma and also often in the delirium of fever; in certain forms of insanity, as in mania, it is often lost for weeks, even months at a time; and lastly, it is never present in dreams.

Color Sense.—I have elsewhere written at large on the color sense, and have only space here to give the facts which bear on the present inquiry. That these are facts the argument referred to I think demonstrates. This faculty appears in the individual at the average age of about five years. It is absent in one adult human being out of every forty-seven; it appeared in our ancestors, as Geiger has shown from linguistic paleonotology, in the Aryan period, probably less than thirty thousand years ago. It is seldom present in dreams, and when it does occur—that is, when any color is seen in a dream—it is generally that color which for good reasons was first perceived by man, namely, red.

The following occurrence illustrates (I think in a striking manner) the usual absence of the color sense during the partial consciousness which occurs in sleep. A man whose hair is white dreamed that he was looking in a glass and saw plainly that his hair was not only much thicker than he knew it to be in fact, but instead of being white, as he also knew it to be, it was black. Now, he well remembered in his dream that his hair had never been black. It had, in fact, been a light brown. He wondered (it is worth mentioning here that wonder or surprise is a prehuman faculty, and is common in dreams) in his dream that his hair should be black, remembering distinctly that it had never been so. (I may say here that memory is a prehuman faculty, and is common in dreams.) The important thing to note about the dream under consideration is that, though it was clear to the dreamer's mind that his hair had never been black, yet he did not remember that it had been brown. For some reason (and I think the reason is quite clear) there was a difficulty in calling up before consciousness any color.

Moral Nature.—The human moral nature belongs to a much later stage of evolution than any of the faculties so far considered. It does not make its appearance in the individual before the average age of fifteen years. It is congenitally and permanently absent in at least forty human beings out of every thousand. It would seem clear, as stated already, from a consideration of our historic ancestors, from the fact

that this faculty rapidly fades out as we ascend into the past, that it cannot have existed in the race more than ten thousand years at the most. It is far more unstable in the individual than are older faculties, such as self-consciousness. It is never present in dreams.

Musical Sense.—Finally, the musical sense (a faculty which is now in act of being born into the race) does not appear in the individual before the average age of about twenty years. It does not exist in more than half the members of the race. It has existed less (perhaps considerably less) than five thousand years in the race. It is never, or almost never, present in dreams, even in the case of professional musicians.

The Scheme of Mental Evolution.—You see now clearly the scheme upon which I suppose the mind (as far as we have got) to have been built. I say advisedly "as far as we have got," because, if the mind has grown in the way set forth, it is still growing and is not built but is in the act of building. No man can ever say positively that his theory (of any fact) is the true one, but I am prepared to say of the above hypothesis that, if it be accepted, it will enable us to understand something of the phenomena of mind as we observe it, whereas if we should prefer to hold, as many do, that the human mind was created independently of any that preceded it by a fiat and *per saltum*, then I say deliberately that there is and can be no such thing as a science of psychology, and that every attempt to investigate or explain, to comprehend or divine the *rationale* of the facts observed as to its origin and growth in the individual must remain forever futile. And if I could find the right words, I would bring home to each one who hears me the inextinguishable conviction that, in this idea of evolution, lie enfolded the mystery of the past, the explanation of the present, and the sure prescience of the future—what we were, what we are, and what we shall be.

The Atavistic Theory of Idiocy and Insanity.—In conclusion, I desire to refer briefly to two corollories which flow from this hypothesis. The first is that if it is correct then all forms of insanity, including all forms of idiocy, are nothing more nor less than cases of atavism. In this view insanity is due to congenital absence or imperfection (leading to breakdown) of some faculty or faculties, such absence or imperfection being due to more or less complete reversion to an ancestral type. In my opinion, this view explains insanity and its numerous forms more completely than these can be explained from any other point of view, and is therefore of great value to the thoughtful student of these phenomena. Upon this view, the comparatively recent origin and rapid evolution of the human mind, and especially the rapid mental evolution of the so-called Aryan peoples in the last four or five thousand years, is almost solely responsible for the large number of cases of insanity in the modern civilized world, since the stability of any form, function, or faculty in any race is dependent upon the time it has existed in that race, and therefore the more recent a faculty is in a race the more frequently will it be found absent, defective, or unstable in the individuals of the race.

Future Development of Mind.—The second corollary, which is even more important than the first, is that, upon the view here set forth, the human mind at present is not formed, but forming; is not completed, but in process of construction. By slow and dubious steps taken in darkness our remote ancestors wearily climbed to simple consciousness. After another immense interval they reached self-consciousness. But that cannot be the end—the cosmic process cannot stop there—cannot, indeed, stop anywhere. Evolution, as far as we can see, has always gone on, is going on to-day, and will always go on. Our old mental faculties are some of them fading out, others advancing toward greater perfection, and alongside of them new ones are springing up, some of which will, without doubt, be of overshadowing importance in the future.

So-called telepathy and clairvoyance seem to be specimens of such nascent faculties. I place in the same class the phenomena of what is often named spiritualism. The labors of the Society for Psychical Research have made it to me plain that these phenomena, as notably in the case of W. Stainton Moses, really exist. And I think that a study of the above-mentioned case, together with that of Mrs. Piper and that of Mary J. Fancher, of Brooklyn, would compel any unprejudiced person to make the same admission. But to me these are not cases in which outside agents are acting on or through a human being, but are cases in which a given human being has faculties which are not commonly possessed. Whether any given faculty, such as one of those now alluded to, shall grow, become common, and finally universal in the race, or wither and disappear, will depend upon the general laws of natural selection, and upon whether the possession of the nascent faculty is advantageous or not to the individual and to the race.

But of infinitely more importance than telepathy and so-called spiritualism (no matter what explanation we give of these, or what their future is destined to be) is the final fact to be here touched upon. This is that superimposed upon self-consciousness, as is that faculty upon simple consciousness, a third and higher form of consciousness is at present making its appearance in our race. This higher form of consciousness when it appears occurs, as it must, at the full maturity of the individual, at about the age of thirty-five, but almost always between the ages of thirty and forty. There have been occasional cases of it for the last two thousand years, and it is becoming more and more common. In fact, in all respects, as far as observed, it obeys the laws to which every nascent faculty is subject. Many more or less perfect examples of this new faculty exist in the world to-day, and it has been my privilege to know personally, and to have had the opportunity of studying, several men and women who have possessed it. In the course of a few more millenniums there should be born from the present human race a higher type of man possessing this higher consciousness. This new race, as it may well be called, would occupy, as toward us, a position such as that occupied by us toward the simple conscious *alalus homo*. The advent of this higher, better, and happier race would amply justify the long agony of its birth through the countless ages of our past. And it is the first article of my belief, some of the grounds of which I have endeavored to lay before you, that a race is in course of evolution.

Treatment of Ulcers by Oxygen Gas.—Possibly the oxygen acts in one or more of the following ways: 1, Diminution of irritation—any dressing applied to an open sore causes more irritation than a mixture of oxygen and pure air; 2, direct stimulation without irritation; 3, the oxygen may oxidize the toxins produced by micro-organisms in the surface of the ulcer—this may apply more especially to the toxins produced by bacilli when present; and 4, as stated by Mr. Stoker, the oxygen has possibly a selective power in its action on micro-organisms present in the ulcer, encouraging staphylococci, which then outgrow the bacilli. Some of the foregoing points are at present under investigation. Here, as yet, we have only the practical results of a few cases to go by, all of which are in favor of the oxygen treatment.—Dr. David Semple, *London Lancet*, May 29th.

ON LITHOTRITY AS THE BEST METHOD OF TREATING LARGE VESICAL CALCULI.[1]

BY HERBERT MILTON, M.R.C.S.,

[illegible]

I HAVE the honor to lay before you a collection of 100 large stones taken from among the 550 cases of vesical calculi that I have had occasion to treat in Egypt since 1892. Of these stones the smallest weighs 50 grams, the largest 995. Of the subjects, 82 were operated on by lithotrity, with 6 deaths; 13 by suprapubic lithotomy, with 4 deaths; 4 by abdominal section, with 3 deaths; and 1 case, in which the stone was half in the ureter and half in the bladder, required a special operation. In the greater number of cases no selection was made with regard to operation; at first, before I had acquired complete confidence in lithotrity, I submitted all large stones to suprapubic lithotomy or to laparotomy; but I have for the last four years practically abandoned in the treatment of large stones all operations except lithotrity. I still, however, practise suprapubic lithotomy for small stones and in young subjects. Under these conditions I have operated some thirty times, with immediate complete suture of the bladder, without losing a patient. My experience with laparotomy has been disastrous. My only successful case was the first one performed, and I was able to remove a stone weighing 995 grams, the largest stone which has ever been successfully removed. The other three cases were all fatal.

The 82 cases treated by lithotrity may be divided into two categories—those in which I have performed the classical operation of Bigelow, and those in which I have introduced a lithoclast through a perineal incision.

Bigelow's operation was performed in 47 cases, with 3 deaths. Of the stones removed in these 47 cases, 37 weighed between 50 and 99 grams, with 1 death; 5 weighed between 100 and 199 grams, with 1 death; 1 weighed 204 grams, another 209, another 240, another 343, and the largest of all 452 grams, or over 16 ounces. Of these 5 cases of very large stones treated by Bigelow's operation, 1 only was fatal, the one in which the stone weighed 240 grams. I think I am justified in saying that no other method has ever given such favorable results. It must be admitted, however, that the operation in such cases is not easy, and I would recommend its practice only to those who have already some experience of litholapaxy. The principal difficulties are:

1. From the great force necessary to crush large and hard stones. This great force may, however, be safely and certainly applied if specially strong instruments are used.

2. From the contraction of the walls of the bladder on the stone, preventing the introduction of the lithotrite and the seizure of the calculus. This contraction is best corrected by the application of hydrostatic pressure, produced by a column of water and continued during three, four, or five minutes.

3. From the length of time necessary for the complete extraction of the *débris*. In some of my operations this has extended to two and one-half hours or even more, and during this long period it was necessary to keep up the strength not only of the patient but of the operator also.

Perineal lithotrity was performed in 35 cases, with 3 deaths. Of the stones removed 18 weighed between 50 and 99 grams, with 1 death; 15 between 100 and 199, with 1 death; 1 weighed 209 grams, and 1 weighed 387. Of these 2 cases, the latter was fatal.

Perineal lithotrity is much easier of performance for large stones than Bigelow's operation, and the results are so favorable that I can strongly recommend it to every surgeon. But its mortality has been greater in my hands than that of Bigelow's operation. I have been troubled with consecutive urinary fistulæ in two of my cases, and the operation entails a much longer convalescence. I therefore am gradually abandoning this operation, performing it only in a few special cases and for demonstration to the students.

The operation invented by Bigelow and named by him litholapaxy is gaining in favor day by day; the limits of its application are removed one by one. Neither extreme youth nor extreme old age need any longer be taken into consideration; the diseased condition of the bladder and of other organs are no longer a contraindication; and I trust that in the immediate future the limitations due to the size and hardness of the stone will entirely disappear.

Progress of Medical Science.

Nervous Cough.—Koch reached the following conclusions: 1. The existence of a true nervous cough cannot be denied. 2. This cough, emanating from a nerve centre, may be diagnosed as such when abdominal and thoracic organs are intact, when one can exclude hysteria, whooping-cough, and beginning phthisis. 3. The monotonous, involuntary cough, always the same in each patient, forms the principal symptom in this affliction. 4. Medication fails. The cough ceases spontaneously after a sea voyage or a trip to the mountains.

Clinical Relations of Auto-Intoxication.—In the course of a recent discussion on auto-intoxication, by members of the Chicago Academy of Medicine, a report of which has appeared in the *Journal of the American Medical Association*, Dr. V. F. Waugh said that the clinical field of auto-intoxication has been gradually widening until about a year ago it was claimed in an editorial in *The London Lancet* that not only is the materies morbi of such diseases of the alimentary tract as cholera, typhoid fever, and all affections characterized by fetor of the stools, generated in the intestinal canal, but also of rheumatism, epilepsy, uræmia, headache, diabetes, chorea, skin diseases, and many of the chronic diseases of the brain and spinal cord. There is one phase of the question, he said, to which very little attention has been paid, though it is rather an important one, and that is the part played by auto-intoxication in fevers. "We know that in all fevers the secretion of the bile is interfered with; it is greatly lessened. We know that the bile is the natural antiseptic of the system; consequently it stands to reason that in all fevers on account of the lack of bile and the increased temperature we have an increased tendency to decomposition of the contents of the alimentary canal. There is in fever, then, necessarily a certain amount of auto-intoxication, and the symptoms of auto-intoxication are added to those which are due to the fever proper. By a system of efficient intestinal antisepsis these can be separated, and when the effects of auto-intoxication have thus been eliminated we find that the severity and the danger of the attack have been materially lessened. It is a question, of course, whether it is better practice to stimulate the liver, already suffering from the fever in such cases, or whether antisepsis should be secured by the use of antiseptic drugs."

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

WM. WOOD & CO., 43, 45, & 47 East Tenth Street.

New York, September 18, 1897.

ORRHOTHERAPY IN ULCERATIVE ENDOCARDITIS.

WHILE recovery from so-called ulcerative or malignant endocarditis is difficult of demonstration, it would be unreasonable to contend that the disease is invariably fatal. On the other hand, in cases in which recovery ensues some doubt might justly remain as to the accuracy of the diagnosis. The knowledge that the lesions present in the cases under consideration are often dependent upon the activity of streptococci and staphylococci, would amply justify the employment of an antitoxic serum when the diagnosis may be ventured. The report of a case of probable ulcerative endocarditis in which successful results attended the use of antistreptococcic serum is therefore not without interest.

The case occurred under the care of Dr. Margaret Dunn, at the Canning Town Medical Mission Hospital, and is reported in *The Lancet* of July 10, 1897. The patient was a girl, sixteen years old, who complained of having had a "cold" for three weeks, with tightness in breathing. There was marked dyspnœa, pulse and respiration were accelerated, and the temperature was 101° F. Cardiac action was rapid and exaggerated, and a loud mitral systolic murmur could be heard, together with a faint diastolic murmur at the aortic area. Under treatment with salicylates no improvement took place. Upon inquiry it was learned that the symptoms had been present about a month. In the course of several weeks aching pains appeared in the left shoulder, together with palpitation of the heart and shortness of breath. There was no previous history of rheumatism, and there had been no rheumatic manifestations beyond a transient erythema the year before.

The patient did not appear very ill, but was bright and lively. There was considerable dyspnœa, but the girl was able to lie down. She complained of palpitation and of slight pain in the left shoulder. There was considerable perspiration without acid odor. Neither rash nor nodules nor anæmia was present. The apex beat of the heart was seen and felt in the fifth left interspace, three inches from midsternum. The area of cardiac percussion dulness was increased to the right. The sounds were muffled at the apex, but a mitral systolic murmur was distinguishable, as well as an aortic diastolic murmur and some pericardial friction sounds. At the base of the right lung dulness on percussion and diminished breath sounds indicated a small effusion.

For a week the patient showed signs of marked general improvement. The dyspnœa lessened, the slight joint pains disappeared, and the temperature gradually fell almost to normal. The physical signs, however, persisted and indicated increase in the pericardial effusion. An aortic systolic murmur became audible, in addition to the mitral systolic and the aortic diastolic. The edge of the spleen was indefinitely felt below the costal margin. During the following week the condition of the patient remained pretty much the same, the temperature rising, however, to 102° F. in the evening. An erythematous rash appeared, which spread by degrees over the limbs and face, disappearing after three days. The amount of fluid in the pericardium and at the right base diminished slightly in amount. The urine was normal throughout. In the next week the temperature remained elevated and the pulse became accelerated. The patient now complained of tenderness on palpation of the spleen, and the physical signs indicated a slight increase in the pericardial effusion.

Treatment with salicylates having been unattended with satisfactory results and the increasing severity of the symptoms suggesting the probability of the endocarditis having assumed a malignant character, it was decided to try the effect of treatment with antistreptococcic serum. Accordingly seven injections were made beneath the skin of the abdomen during a period of two weeks, at intervals of a day or two, in amounts varying from two and one-half to twenty cubic centimetres. During this period sharp pains and friction sounds appeared in the left axilla, and a transitory presystolic murmur became audible. Ultimately, however, the temperature declined, improvement took place in the physical signs, and the case proceeded to complete recovery.

The diagnosis of ulcerative endocarditis was based upon the seriousness of the patient's condition, the hectic type of the temperature and its persistent elevation in the absence of fresh rheumatic manifestations or increase of those present, the appearance and disappearance of the heart murmurs, and the increase in the size of the spleen. Unfortunately bacteriological examination of the blood was not undertaken until after treatment with the antistreptococcic serum had been instituted, and then no micro-organisms were found. The possibility of typhoid fever was excluded by the absence of characteristic symptoms excepting high temperature and increase in the size of the spleen. Acute tuberculosis was less closely simulated, and the outcome of the case apparently decided against this possibility, even had there been any doubt

Camden Medico-Surgical Society.—At a stated meeting of this society, held on September 6th, Dr. H. F. Sherk read a paper on the discovery of ether as an anæsthetic.

THE CACHEXIA OF CANCER.

Cancer in Great Britain is increasing at a most alarming rate. The proportional mortality is more than four times greater than it was a century ago; as a consequence, attention is attracted to every phase of the disease. Much still remains to be discovered, although recent progress has completely revolutionized our knowledge on the subject. Concerning the cachexia of cancer, Mr. W. Roger Williams, writing in the *Edinburgh Medical Journal* for June, 1897, says that "after a cancerous growth has existed for a variable time, which is generally rather long, the patient's health begins to suffer, even in the absence of ulceration, hemorrhage, etc. Pallor, weakness, emaciation, and loss of appetite are among the most obvious manifestations. These, as the disease progresses, become greatly aggravated, the pallor taking on a peculiar earthy or straw-colored tint; while other indications of profound disturbance of the general nutrition arise, which, when the malady runs its natural course, eventually determine death from asthenia. This condition is the cancerous cachexia. It is noteworthy that cachectic symptoms never precede the outbreak of the primary disease; from this we may infer that they are a consequence of its local progress. We may, I think, best interpret these symptoms as the result of a general toxæmia." Mr. Williams then traces the disease through its various stages, terminating in asthenia, and states that out of ninety uterine cancer cases that ran their natural course under his observation, sixty-four thus ended; and in twenty-four out of forty cases of breast cancer the final results were similar. These conclusions as to the existence of a special cancerous cachexia are not in accordance with the views held by many observers of the disease. The condition described above is attributed by them rather to ulceration of the growths and subsequent absorption of the septic products, or to repeated hemorrhages.

MUNICIPAL WATER SUPPLY.

Water is a question of perennial interest. Voluminous of late has been the literature concerning the necessity of an adequate and unpolluted supply of water, and it may appear to some that the subject is in danger of being overwritten, but it is a matter that will bear much discussion. The truth cannot be too strongly impressed upon the public that, taken all round, the supply of pure, unadulterated water for municipal purposes is defective, and that the large cities of Europe are far in advance of this country in this respect. Prof. W. T. Mason, in a lecture delivered before the Franklin Institute in March last, says: "The day is past when we could feel a sense of superiority over the crowded millions of the old world, because of the relative magnitude and consequent initial purity of the sources of our water supplies. Europe has of late years expended much labor and capital in substantial plants that make for sanitary betterments, while we have continued upon a conservative course, forgetful that our populations and industries have been growing, and that the river our fathers drank from with pleasure and safety has become charged with the refuse of up-stream communities, and converted into what may be properly styled the county sewer."

The most radical difference between the European and the American systems is that in this country the water is delivered raw, while in many places in Europe it is carefully filtered. Hence it stands to reason that the greatest possible attention should be paid to the storage of the water, as regards both the reservoirs and house tanks. Unfortunately it is to be feared that this is not always the case. In New York City a recent examination of the water tanks in the tenement-houses has shown them in many instances to be in a most filthy condition, most of them apparently not having been cleaned since they were first erected. There are many otherwise good citizens who are averse to changing the present order of things and introducing extensive improvements, on account of the cost. Professor Mason says in regard to this matter: "There is, believe me, no system of filtration or other efficient method for purifying a polluted water so expensive but that a community can well afford to introduce it rather than to drink a dangerous water in its raw state; and this, too, from purely economic considerations, and leaving out of sight all ethical questions whatsoever."

ENGLISH CONTRACT DOCTORS IN THIS COUNTRY.

The Lancet of July 24th publishes a very voluminous letter from an English medical man who is practising in Lower California. This gentleman bitterly bewails his fate, and strongly warns practitioners in England who may be thinking of emigrating either to this country or Mexico, to take warning by his unfortunate experiences, and to ponder seriously ere they leave their native soil. Some of the advice given in this letter is certainly judicious and to the point. Dr. Millican says: "First, let intending emigrant doctors be sure that what appears to them a large salary at home is of the same relative value in the country whither they propose to go. Secondly, have everything reduced to writing in such form as to be cognizable by the courts of both countries. Thirdly, if it be the United States, have an agreement signed in England before starting, and embodying a clause to the effect that a new agreement embracing the same terms shall be executed in America on landing. Fourthly, insist that the facts upon which any promised advantages are based shall also be reduced to writing. Fifthly, do not take any 'collateral advantages' as part remuneration. Get money value for your services, and pay cash for your collateral advantages when you have found out what they are worth. Lastly, insist upon a clause securing your return passage in any case."

Unfortunately for Dr. Millican, through ignorance he did not protect himself by acting up to any of these clauses. He has learned wisdom by bitter experience,

and according to the tale he unfolds in *The Lancet*, luck has been decidedly against him. As a matter of fact, here in this country there is little scope or chance of success for foreign physicians. America can easily supply her needs in that respect with the home-made article.

OUR CABLED REPORT FROM MOSCOW.

It is with no small feeling of satisfaction that we refer our many readers to the comparative fulness and accuracy of our cabled report of the recent meeting of the International Medical Congress at Moscow. Although occupying no more space in the MEDICAL RECORD than the reports of other meetings within easy reach of home, the degree of trouble and amount of expense in securing the one in question can hardly be appreciated by the subscriber who is being educated to believe that everything is possible with his favorite journal. The latter estimate of resources applies with particular directness to the MEDICAL RECORD, as it is the only journal of any kind in America that has gone to the expense of securing promptly and accurately a cabled report of the Moscow meeting. It is in keeping with this spirit that we strive to be on the alert for anything and everything that may keep our readers fully abreast of the times.

News of the Week.

Philadelphia County Medical Society. — At a stated meeting of this society, held on September 8, 1897, Dr. Joseph Price exhibited a large number of varied and interesting specimens removed by abdominal section; among them, the cæcum and four inches each of ileum and colon, removed on account of malignant disease; a portion of ileum removed on account of perforation, possibly typhoid; and also a number of extra-uterine gestation products. He pointed out that in his experience rupture of ectopic gestation cysts occurs with much greater frequency during the summer months than during any other period of the year, and that ectopic pregnancy occurs with noteworthy frequency in women in whom lactation is prolonged, either for the purpose of averting pregnancy or from other cause. It seemed to be the consensus of opinion that when removed neoplasms, diagnosed as malignant, failed to recur, there had been an error in diagnosis.

Pathological Society of Philadelphia. — At a stated meeting of this society, held on September 9, 1897, Dr. A. Ferree Witmer exhibited a specimen of endothelioma of the spinal dura, and related the history of a case. Dr. A. A. Eshner exhibited specimens from a case of uræmia, including large, white, fatty kidneys and broncho-pneumonia, with little if any hypertrophy of the heart. A noteworthy feature of the case was the temperature, which ranged between 103 and 104° F., illustrating the fact that uræmia is not necessarily attended with normal or subnormal temperature.

A Gift to the Charity Hospital in New Orleans. —Mrs. D. A. Milliken, widow of the late Richard Milliken, of New Orleans, has announced her purpose to erect and endow a large hospital for children, to be an annex to the New Orleans Charity Hospital. The hospital is to be a memorial to her husband.

St. John's Guild Floating Hospital.—The statistics for the past summer of the Floating and Seaside hospitals of St. John's Guild, show that on the Floating Hospital 43,468 women and children were cared for and 8,011 salt-water baths were given; and that at the Seaside Hospital, at New Dorp, Staten Island, 1,556 children were received and 14,151 hospital days of treatment were given. Many times during the season more sick persons were at the wharf waiting to be taken aboard the Floating Hospital than there were accommodations for, and the managers of this beneficent charity will therefore provide a second floating hospital for next summer

An International Epidemiological Bureau.—The editor of *Janus*, a review published in Amsterdam, desires to establish an international system of reporting epidemiological data, and thus to give warning of epidemic storms in somewhat the same way that atmospheric disturbances are now heralded, so that precautionary measures may be taken. As soon as arrangements can be made, it is purposed to publish a bi-monthly record of the progress of epidemiology, which shall include: (1) Current statistics of the morbidity and mortality from epidemic diseases—contagious, miasmatic, and miasmatic-contagious—from states, provinces, and cities for which such data are available, accompanied when possible by the meteorology; (2) original observations on epidemic diseases; (3) historical records of epidemics in particular countries and cities, and their periods of prevalence and quiescence; (4) special communications on subjects of epidemiological interest.

The Losses of Spain in Cuba. — Dr. de Larra y Cerezo publishes, in *La Medicina Militar Española*, some statistics of the morbidity and mortality among the troops of the invading army in Cuba. During the month of May there were 38,692 admissions to the general hospitals; of these 523 died, and 33,739 were discharged. In the yellow-fever hospitals the admissions for the same time were 814, of whom 226 died and 406 were discharged. In the general hospitals in Havana there were, on the 1st of June, 4,709; there were admitted during the month, 9,931; discharged, 8,798; died, 270; and there remained in hospital, 5,512, on July 1st. Of yellow fever the statistics are: Patients in hospital on June 1st, 213; admitted during the month, 677; died, 170; and remaining in hospital, 331.

The Light of Teutonic Science Deflected from America.—The German universities have had new regulations made for them by the various state governments, under which many American medical students will be excluded from the clinics. The Berlin physicians, however, are not yet satisfied, and, it is

said, have petitioned the government to draw the lines still closer, so as not to admit students from American medical colleges or universities, unless they pass a preliminary examination.

A Congress Memorial in Moscow. — It has been proposed by a number of wealthy citizens in Moscow to endow an infirmary for epileptics and the weak-minded of both sexes, to commemorate the congress.

Obituary Notes.—Dr. Caleb Lyon, of Rossville, Staten Island, died at his home, on September 11th, of heart and kidney trouble. He was born in this city, fifty-five years ago, and was graduated from the Albany Medical College in 1871.—Dr. Braxton Hicks, F.R.S., formerly physician-accoucheur to Guy's and afterward to St. Mary's Hospital, London, died August 28th, aged seventy-two years. He suffered an attack of influenza three months ago, from which he never fully recovered.—Dr. J. C. Howden, of England, died on August 17th. He was superintendent of the asylum for the insane at Montrose, Forfarshire, from 1857 until last June, when he resigned on account of ill health. He early recognized the value of the out-door system of treatment of the insane, and carried it out in the asylum under his charge. Three years ago he had an attack of apoplexy, but recovered sufficiently to resume his duties.

English Comments on the Congress.—The correspondents of the English journals are not extravagant in their praise of the Moscow congress. As is usual at such gatherings, absolutely no provision was made to facilitate the work of the reporters for the medical press. The correspondent of the *British Medical Journal* writes, in relation to this: "In a country where practically a press is non-existent, it would be perhaps ridiculous to expect that the convenience of the members of the press of other countries should be carefully considered; but whether it was expected or not, it certainly has been most studiously neglected. The bureau is such only in name; in it one finds neither information nor officials, nor anything, indeed, more than tables, pen, and ink. It rests therefore with the individual correspondent to seek such information as can be gleaned from overworked secretaries and personal observation." Our own correspondents have told us the same story, and the complete and accurate reports which they have sent us were obtained only by following each speaker and taking down his words as they were spoken. The officials of the congress gave them no assistance whatever. *The Lancet* representative complains of the lack of toilet conveniences, "of the shameful inadequacy" of which, he writes, "a plain word must be spoken. One urinal and one water-closet were placed at the disposal of the whole congress, and both were in the same little wooden hut, divided from each other by no partition. Moscow is, according to European ideas, very inadequately supplied with latrines, while the unblushing publicity of the East concerning the performance of all the offices of nature to a great extent prevails; but those responsible for the arrangements of the public meeting in the Manége ought to have remembered that the meeting was an international one, and not an Oriental one." Finally, the *Medical Press* says that the Russian government excluded Jewish physicians from the congress—a fact, if it is a fact, which greatly surprises us, for it had been declared officially that no distinction would be made against Hebrews on this occasion. "Naturally enough," our contemporary says, "much irritation has been caused by the exclusion of Jews from the Moscow congress. An incident in connection therewith has been referred to by the Moscow correspondent of the *Standard*. At one of the dinners held in honor of the congress, a heated discussion took place across the table between a Russian member and one of the best-known German professors, *à propos* of the prohibition, in the course of which the former used threatening gestures toward his *confrère*, who was an elderly man. It was only after considerable difficulty that an adjustment of the quarrel was brought about. Such asperities, of course, should have no place at the meetings of scientific men. But neither should any narrow-minded exhibition of religious or racial intolerance be permitted by those responsible for the organization of the *réunions*."

Smuggled Phenacetin.—A saloon-keeper in Hoboken was arrested recently for having four hundred ounces of smuggled phenacetin in his possession. The box containing the drug was found in the icebox of the saloon.

The German Society of Naturalists and Physicians.—The sixty-ninth annual meeting of this association will be held at Brunswick, September 20th to 25th, under the presidency of Dr. v. Lang, of Vienna. The subject of scientific photography and its application to medicine is one of the most important of the set discussions.

A Perilous Post.—Sir Joseph Tholozan, physician to the late shah of Persia, died a few weeks ago, and a French paper says that it is currently reported that he was poisoned. He had been the trusted confidant of Nasr-ed-Din for over thirty years, and was acquainted with many of the secrets of the court, and his removal was desired on this account by the new government. After the death of the shah Sir Joseph Tholozan wrote to a friend in France, stating that he intended to resign his post because his life was not safe, and it would appear that his fears were only too well founded. His predecessor at the Persian court is stated to have been done away with in the same manner.—*British Medical Journal.*

Yellow Fever.—There is little to cause alarm in the situation in the towns bordering the Gulf, where yellow fever has appeared. The disease has naturally spread from Ocean Springs, where it was first discovered, to other places. The largest number of cases is in Edwards, Miss., where forty-two persons are reported sick, many of them with yellow fever. At New Orleans several new cases are reported each day, but the sanitary authorities are doing very efficient work and there is no apprehension that the disease will assume epidemic proportions. The fever is in a mild form, and the mortality thus far has been light.

Reviews and Notices.

THE MENOPAUSE. A Consideration of the Phenomena which Occur to Women at the Close of the Child-Bearing Period, with Incidental Allusions to their Relationship to Menstruation. Also a Particular Consideration of the Premature (Especially the Artificial) Menopause. By ANDREW F. CURRIER, A.B., M.D., New York City. New York: D. Appleton and Company. 1897.

THE main object of the author in writing this book, he tells us, was to divest this physiological period of the atmosphere of terror with which it has become surrounded. "The menopause," he says, "is *not* a dangerous time or experience for the majority of women, any more than puberty is. The majority of women pass through it with as little incident or discomfort as they experience at puberty." Still there are some who suffer more or less, and these the follower of Dr. Currier's simple directions will be in a position to relieve greatly. In some cases the hastening of the menopause by surgical measures is advised, but we are glad to find that the author is quite conservative when he comes to discuss the indications for operation.

ENCYKLOPAEDIE DER THERAPIE. Von OSCAR LIEBREICH, Dr. Med., Geheimer Medicinalrath, o.ö. Professor der Heilmittellehre an der Friedrich-Wilhelms-Universität, unter Mitwirkung von MARTIN MENDELSOHN, Dr. Med., Privatdocent der inneren Medicin an der Friedrich-Wilhelms-Universität, und ARTHUR WÜRZBURG, Dr. Med., Kgl. Sanitätsrath, Bibliothekar im Kaiserlichen Gesundheitsamte. I. Band, 2 Abtheilung, und II. Band, 1 Abtheilung. Berlin: August Hirschwald. 1896 and 1897.

THIS first number of the second volume of this latest and best of the German works on therapeutics contains the titles from Diaphoretica to Flaschenbouillon, and embraces a consideration of such important subjects as digitalis, diphtheria, diuretics, dyspnœa, iron, eclampsia, suppuration, electrotherapeutics, empyema, endocarditis, epilepsy, euthanasia, obesity, and fever. The second number of volume one was delayed in transmission and was consequently not reviewed in its proper place. It is of the same general excellence as the other parts of the series. It contains the titles from Auge to Cera, including eyes, autointoxications, baths and balneotherapy, bacilli and bacteria, professional neuroses, lead-poisoning, blindness, blood and blood-poisoning, gastro-enteritis, bronchitis, broncho-pneumonia, bubo, carbuncle, carcinoma, cataract, and many others. The articles are excellent of their kind, concise but complete, and of just the sort that a busy man wants.

A SYSTEM OF MEDICINE. By Many Writers. Edited by THOMAS CLIFFORD ALLBUTT, M.A., M.D., LL.D., F.R.C.P., F.R.S., F.L.S., F.S.A., Regius Professor of Physic in the University of Cambridge, Fellow of Gonville and Caius College. Volume III. New York: The Macmillan Company. 1897.

WE call this the third volume because the title-page says it is, but the editor and publishers are apparently unable to make up their minds as to its proper place in the series. The cover says 3, the title-page says 3, the editor in his preface calls it 2, and on the last page is printed "end of Vol. II." This does not inspire one at first glance with confidence in the systematic arrangement of the work as a whole, and neither does the fact that it has been found necessary to insert several addenda to articles in this and preceding volumes. The editor unfortunately placed the infectious diseases in the early volumes of the series, with the inevitable result that, before the last volume is issued, the first will be relegated to medical history. In these days of rapid advances in the science of bacteriology such an arrangement is regrettable. The issue of this volume was delayed in order to profit by the report of the British commission on vaccination. The report itself was scarcely worth waiting for, but it is a pity the book was not delayed a little longer to enable the writer on yellow fever to profit by Sanarelli's discovery of the bacillus icteroides. It is hardly fair, we admit, to criticise a single volume in a series, since apparent omissions may be repaired by articles in later volumes, but we cannot understand why the section on "infective diseases of chronic course" should include only tuberculosis, leprosy, actinomycosis, and Madura foot. Tuberculosis fills less than forty pages and the section on its treatment just seven lines, no mention whatever being made of the labors of Koch and others in this direction, unless we accept as such the statement that "there is no specific treatment for tuberculosis." In the article on leprosy, also, the work of Carrasquilla, of Bogotá, is completely ignored. The writer of the article, Dr. Abraham, admits the possibility of contagion, but evidently regards it as a minor factor in the spread of the disease. The author of the paper on typhus fever says that the disease is hardly known in the tropical and subtropical parts of North and South America; a trip to Mexico would convince him of his error. The article on malaria is by Dr. Osler, of Baltimore. It is a disappointingly brief and superficial sketch, unworthy of the author. Surely malaria is as important a subject as rabies or anthrax, yet in this work the editor has allotted to the latter twenty-four and twenty-eight pages respectively, while malaria is tossed off in twenty-two pages.

REFERENCE BOOK OF PRACTICAL THERAPEUTICS. By Various Authors. Edited by FRANK P. FOSTER, M.D., Editor of the New York *Medical Journal* and of Foster's Encyclopædic Medical Dictionary. Volume II. New York: D. Appleton and Company. 1897.

WITH the second volume this excellent work is completed and is rendered immediately available by means of the general index and index of diseases and remedies as a book of therapeutic reference. A supplement of nearly fifty pages bears witness to the rapid strides in medical science, since it is filled chiefly with matter relating to knowledge acquired since the appearance of the first volume. The work is well printed and well bound, and the brief articles on every subject relating to the treatment of disease are excellently written and in the main satisfactory as to the information they impart.

SUPPRESSION AND PREVENTION OF LEPROSY. By ALBERT S. ASHMEAD, M.D., Late Foreign Medical Director, Tokyo Hospital, Japan. Norristown, Pa.: *Herald* Printing and Binding Rooms. 1897.

THIS is a reprint of a number of letters and of essays by the author on subjects connected with the suppression of leprosy. The author, who at first opposed strenuously the proposed leprosy congress at Berlin, now gives his adherence to it. Dr. Ashmead's belief is that Hansen's discovery of the leprosy bacillus has been of no use and can be of no use to the leper, that leprosy is absolutely incurable, and that the only safety for the well is to isolate all lepers strictly. Consequently the proposed leprosy congress will be worse than useless if it discusses anything but isolation. This shows that Dr. Ashmead has firm convictions, but it can scarcely be accepted as a specimen of scientific reasoning.

EYE STRAIN IN HEALTH AND DISEASE. With Special Reference to the Amelioration or Cure of Chronic Nervous Derangements without the Aid of Drugs. By AMBROSE L. RANNEY, A.M., M.D., Author of "Lectures on Nervous Diseases," "The Applied Anatomy of the Nervous System," etc.; Late Professor of Nervous Diseases in the Medical Department of the University of Vermont and of the Anatomy of the Nervous System in the New York Post-Graduate Medical School, etc. Illustrated with 38 Woodcuts. Philadelphia: The F. A. Davis Company. 1897.

THIS is an interesting book, for it deals with the marvellous, which always makes entertaining reading. For example: A man had failed mentally to such a degree that he had to be told what clothes to put on, would chew a bolus of food for an hour unless told to swallow it, was absolutely unable to do any work, and had suffered for six months terribly from insomnia. He had four degrees of hyperphoria. This was corrected by a graduated tenotomy of the left superior rectus. "The night following the operation he slept soundly all night. He arose the next morning, dressed himself without aid, and drank three goblets of milk before the rest of the family were up. He then sat down and ate a good breakfast, finishing as quickly as any one." Numerous other instances are reported of cures, by correcting visual defects, of melancholia with delusions or suicidal impulses, insomnia, and nervous prostration of many years' standing. The book

deals with the influence of eye strain in the causation of headache and neuralgia, chorea, insomnia, chronic gastric and digestive disturbances, epilepsy, nervous prostration, and insanity, as well as of various other affections of the eye itself. Dr. Ranney is an earnest believer in his theory, and the many facts he cites afford strong evidence in favor of it, even after we eliminate the chance of coincidence and the possible effect of "suggestion." Those who are inclined to absolute incredulity must be reminded of the common experience that some patients, said to be suffering from eye headache, have really been relieved by proper glasses, and we cannot reject on the mere argument of improbability evidence such as that furnished in abundance by Dr. Ranney. At least, before condemning the author the sceptic should in fairness read his book.

THE VERTEBRATE SKELETON. By SIDNEY H. REYNOLDS, M.A., Trinity College, Cambridge; Lecturer and Demonstrator in Geology and Zoology at University College, Bristol. Cambridge: At the University Press. 1897.

THOUGH the title does not suggest it, an account is included of the skeleton of the lowest Chordata; the description of the general characters of each group is first given, and then of the subdivisions. A large field has been covered without extending the work beyond the limits of a moderate-sized handbook.

The drawings, which are numerous, are original or from photographs by the author and his sister. There is a very full index.

The volume is one of the Cambridge Natural Science Manuals. The author is to be congratulated on the completion of an arduous and praiseworthy task in a very successful manner.

FADS OF AN OLD PHYSICIAN. A SEQUEL TO "PLEA FOR A SIMPLER LIFE." By GEORGE S. KEITH, M.D., LL.D., F.R.C.P.E. London: Adam & Charles Black. 1897.

THIS is, as the title indicates, a sequel to the author's "Plea for a Simpler Life," noticed in the MEDICAL RECORD some time ago. Various matters of general and professional interest are treated in a pleasing manner. Many views advanced may be regarded as fads—hence the title. Starving, stimulants, relief of pain and sleeplessness, cancer, self-massage, and methods of preserving health, are some of the topics worth reading.

THE LIVER OF DYSPEPTICS, AND PARTICULARLY THE CIRRHOSIS PRODUCED BY AUTO-INTOXICATION OF GASTRO-INTESTINAL ORIGIN (CLINICAL, ANATOMO-PATHOLOGICAL, PATHOGENIC, AND EXPERIMENTAL STUDY). By DR. EMILE BOIX, Interne Lauréat des Hôpitaux de Paris; Medaille d'Or, Concours de 1893; Medaille d'Or des Épidémies (Cholera, 1884). Authorized Translation, from the Latest French Edition, by PAUL RICHARD BROWN, M.D., Major and Surgeon, United States Army. New York and London: G. P. Putnam's Sons, The Knickerbocker Press. 1897.

THE work was well worth the translation, and Dr. Brown has done it well. Causes of cirrhosis other than those referable to alcohol and its abuse are taken up. The term "dyspeptic cirrhosis" is employed as a handy means of expression. In Part III. a series of experiments is given, showing the influence of the various dyspepsias in the etiology of cirrhosis.

VORLESUNGEN ÜBER KRIEGSCHIRURGIE. Von DR. L. LÜHE, Generalarzt a. D. Berlin: August Hirschwald. 1897.

THIS work consists of twelve lectures on military surgery given by the author to German army surgeons. Operative technique is considered only in so far as it differs from that of civil surgery. The first part of the work is devoted to a description of the wounds inflicted by modern projectiles, based chiefly upon the experiments conducted by the German commission. The author then describes the duties of the surgeon during and after battle, the aseptic and antiseptic methods which are practicable in the field, and the nature of the surgical treatment which is demanded on the firing-line, at the first dressing-station, and in the field hospital. He differs from most authors in advising that wounds be not exposed by litter bearers for the application of dressings, and that provisional splints be applied over the clothing. The author is remarkably well acquainted with the work of American surgeons and quotes American writers more frequently than any others outside of Germany. The work is eminently practical, and contains many suggestions which will prove of value to the army surgeon.

Society Reports.

TWELFTH INTERNATIONAL MEDICAL CONGRESS.

Held in Moscow, August 19, 20, 21, 22, 23, 24, 25 and 26, 1897.

Special Report to the MEDICAL RECORD.

SECTION IN SURGERY.

Continued from page 420.

First Day—Friday, August 20th.

The Surgery of the Lung.—DR. TUFFIER, of Paris, read a long paper on surgery of the lung, particularly of tuberculous cavities and pulmonary gangrene. The paper was one that greatly interested those present, in spite of its length, nearly two hours being occupied in its delivery. It was an exposition of the indications for surgical intervention in various pulmonary affections, and a plea for the more general resort to the use of the knife in such cases.

DR. MACEWEN, of Glasgow, agreed in the main with Dr. Tuffier, but considered that certain phases of the practical side of the question and certain details in technique justified some additional remarks. The physics of the pleural cavity were still not entirely settled. The general belief was that the opposing surfaces of the pleuræ were kept in apposition by atmospheric pressure. Personally he did not believe this traditional opinion, but considered that the phenomenon was best explained as the result of molecular adhesion. When two perfectly smooth surfaces, such as two pieces of polished glass, were firmly pressed together, they adhered. The same happened with regard to the two pleural surfaces. As the result of this, when the pleura has been slightly incised, though the atmospheric pressure has been relieved of its influence, parts of the pleura in the neighborhood adhere and give rise to a collection of air in the pleural cavity. This soon causes symptoms of dyspnœa. Puncture relieves it for the time being, but accumulation begins again and reproduces the symptoms. Further aspiration has only the same result. If the pleura be freely incised, however, these adhesions fail to take place, and the accumulation of air in the pleural cavity, with the consequent symptoms, does not take place. Hence in all cases of operations involving the pleura, free incision should be practised. With regard to tuberculous cavities, personal experience had taught him the following methods of treatment for varying circumstances: In small tuberculous cavities it was sufficient to resect three or four ribs, and allow the cavities to collapse. Large cavities should be freely incised, emptied, and drained. Very large cavities should be thoroughly scraped and packed with iodoform gauze. The improvement noted after such procedures was often immediate and striking. The general condition improved, and diseased foci in the other lung were gradually shut off. Such improvement had even been observed to follow in cases in which disintegration of the operated lung took place.

DR. COROMILAS, of Calamata, Greece, read a paper dealing especially with surgical interference with tuberculous cavities. His paper was a repetition of what had been said by Tuffier, but illustrated how

widespread is becoming the realization that surgical interference in pulmonary affections, even in extensive tuberculous processes, is perfectly justifiable.

Dr. Fabrikant, of Kharkov, spoke of radical extirpation of diseased localities down to healthy tissue, when the affection is not too far advanced, early operation after careful diagnosis being the requirement in lung surgery.

The Diagnosis of Pleural Adhesions. — Dr. Sapechko, of Kiev, read a communication with this title. After pointing out the difficulties of exact diagnosis in the matter with our present methods, he described his own mechanical process for their diagnosis. When operations are to be made on the lungs for tuberculous cavities or abscess or gangrene, it is important to have the incision at a point of adhesion. The speaker inserts as far as the pleura a cannula, to which is attached a U-tube manometer containing decinormal physiological salt solution. Sinking of the liquid shows the existence of negative pressure; hence non-adherence of the pleura. When the level of the liquid remains undisturbed, adhesions are present. Dr. Sapechko has never lost a patient from infection of pleura after using this method. He suggested that when adhesions cannot be found they may be produced by the introduction of an irritating though sterile liquid. Experiments in this line have succeeded in animals, and promise to lessen greatly the dangers of surgical interference in the lungs.

Perityphlitis.—Dr. Roux, of Lausanne, read a paper with this title. He considered that not enough importance was attached in Europe to the surgical treatment of the affection. He had seen a great many cases, and had operated in a number. He did not consider that all cases presenting symptoms located in the right iliac fossa should be operated upon, as many of his American colleagues seemed to think, but he considered the affection properly a surgical one. Such opinions as that of Leyden, of Berlin, that practically all cases of appendicitis got well in time and that the fulminant cases were fatal anyhow even under surgical treatment, he could not consent to. He believed that death took place from peritonitis after secondary perforation, and he thought the patient should not be moved at all, especially not for a disturbing ride to a hospital. The abscess became frankly localized in from five to seven days, and then could be opened from the flank, the rectum, or the vagina. One must always remember that there is a meso-appendical form of abscess, in which the pus is located behind a fold of peritoneum. In opening, the operator may come upon the serous or seropurulent exudate, which is always found in the peritoneum, due to the presence of the inflammatory process, and erroneously think that he has opened the abscess. This form resembles a generalized peritonitis, but if one waits for a few days localization takes place fully and the case is easy of treatment. To operate during the first period in such cases means the death of the patient. The speaker believed in expectant treatment until firm inflammatory adhesions have walled off the exudate. He did not agree with American surgeons, who thought we could operate soon enough as to suppress the appendicitis; this would be the ideal way, but could be put into practice only during the first few hours of the attack. It would be realizable only if all our patients lived in hospitals. When a patient has had even one attack, Dr. Roux would advocate the removal of the appendix some six or eight weeks after recovery, for there exists no other means of preventing recurrences. When operating in the interval he always separates the muscle fibres of the belly wall in the direction they run, in order to avoid subsequent hernia or eventration. He avoids thus the cutting of nerve fibres, which have a trophic influence on the muscle fibres and keep them in proper tone to retain the abdominal viscera. If the operation in the interval between attacks is difficult of performance, it is a sign that the operator has not waited long enough, for it should be extremely easy.

Relapsing Appendicitis.—Dr. Kümmel, of Hamburg, read a paper with this title, which was a review of one hundred successful resections of the vermiform appendix. In addition to his own cases, the speaker had collected the statistics of a nearly equal number of cases of relapsing appendicitis, in which the operation had been refused. In these cases the mortality after three years was greater than in the operated cases, while the morbidity consequent upon the recurring attacks made the second series of cases incomparably worse.

Dr. Sonnenberg, of Berlin, reported two hundred and fifty operative cases of appendicitis, exclusive of several of tuberculous disease of the appendix. There were sixty-six cases of simple appendicitis, one hundred and fifty-six of perforative appendicitis, and twenty-eight of gangrenous appendicitis. In the two hundred and fifty cases there were forty-three deaths. This mortality of seventeen per cent. represents the mortality of the disease, not of the attacks, while statistics so far have been mainly concerned with the mortality of the attacks. The forty-three deaths were encountered in cases of perforative appendicitis with complications (as lung and pleural affections, thromboses, peritonitis, etc.) and in cases of gangrenous appendicitis. The operated cases of simple appendicitis and of simple perforative appendicitis gave no deaths. It is to the surgeons, he said, that we owe our knowledge of diseased conditions of the appendix. The most interesting thing in the process is the tendency very often for important pathological changes to go on for a long time without noticeable symptoms. These so-called latent cases manifest themselves first in a stormy attack with severe clinical symptoms, usually caused directly by perforation of the appendix. This perforation is, however, only the last link in the chain of recurring pathological changes in the chronically affected appendix. In sixty per cent. of seemingly first attacks of appendicitis perforativa without complications operated upon, extensive pathological changes that had evidently been going on for a long time were found in the appendix. The same state of affairs was recognized in seventy-four per cent. of the cases of perforative appendicitis with complications, and in practically all the cases of gangrenous appendicitis. Of these one hundred and twenty-four patients, only seventeen had had any symptoms before their attack. It is impossible to imagine, however, that such cases should be absolutely symptomless, so that it is our duty to pick out the symptoms. It is wonderful, the speaker said, to see how seemingly disconnected with the appendix the symptoms may seem to be which point to the insidious development of pathological changes in the appendix. Great success in the treatment of appendicitis awaits the success of our efforts in this direction. As to the question whether the appendix should be searched for and removed, Dr. Sonnenberg believed that this should be done in all cases in which it does not endanger the patient's life. It was his general rule to leave the appendix *in situ* only when there was danger of breaking up the adhesions that protect the general peritoneal cavity, or when there was danger of injuring the cæcum and so causing subsequent perforation, or when it seemed probable that in the process of healing the appendix would be completely absorbed with the exudate. While in most other conditions where medicine and surgery touch the domain of the surgeon has been narrowed, here it has been widened, and the sooner we recognize that it is often properly a surgical, not a medical condition, the better. In simple appen-

dicitis it is in the interval between the attacks that the operation should be done, and this is extremely advisable whenever there has been a frank attack. Out of sixty cases of simple appendicitis, Dr. Sonnenberg had operated only twenty-four times during the attack.

The Indications for the Lumbo-Sacral Incision in Suppurative Appendicitis. — Dr. Grinda, of Nice, read a paper setting forth the indications and advantages in the operative treatment of suppurative appendicitis of an incision following the external border of the sacro-lumbar mass of muscles, curving in at the lower part, prolonged parallel to and one finger's breadth above the iliac crest to about three centimetres from the anterior superior iliac spine. This lumbo-iliac incision is indicated in all cases in which the local signs permit the diagnosis of appendicular abscess, especially in the cases in which there is pain in Petit's triangle and in which McBurney's point is little if at all tender. With this incision better drainage is secured, there is less danger of wounding the small intestines which so often lie adherent above the inflammatory exudate around the appendix, there is less danger of infection of the general peritoneum, and it is also much easier to get at the appendix itself for a radical operation. Especially is this incision to be commended when the general symptoms indicate appendicitis and nothing points to a special localization of the suppurative process.

Dr. Le Dentu, of Paris, agreed with Dr. Roux as to the necessity for waiting until the process had thoroughly localized itself. He counselled especially the operation in the interval between attacks. He did not think that the surgeon should spring upon the patient at the first sign of trouble with the appendix. Sudden perforation with general peritonitis or fulminant gangrene of the appendix was too rare to influence the general rule of action in the matter.

Dr. Lavista, of Mexico, thought that the American surgeons as a rule were sufficiently conservative. They, too, counselled the operation *à froid* in relapsing cases of simple appendicitis. Acute cases must, however, be watched with extreme care, as the patient's danger is always great and the surgeon must be ever prepared to operate.

The Chairman said that Dr. Senn, of Chicago, had asked to be excused, so that the section would unfortunately not have the pleasure of listening to his paper on "The Uses of the Omentum in Surgery." The paper was therefore read by title.

Treatment of Intestinal Occlusion.—Dr. A. von Eiselsberg, of Königsberg, read a paper on the treatment of inoperable stricture of the intestinal canal and of fæcal fistula by the complete shutting off of the affected portion of the intestine. In carcinomatous strictures the operation gives complete relief from pain and the painful sense of pressure that so often characterizes these cases. In fæcal fistula after appendicitis, when the usual methods for the closure of the fistula have failed, the shutting off of the chronically inflamed portion of intestine and the bringing together of two healthy portions are indicated.

Dr. R. von Baracz, of Lemberg, read a paper on the same subject. In a report of seven experiments which he had made on dogs, the speaker brought out the dangers of leaving the shut-off portion of intestine in such cases unoccluded, and demonstrated, by means of specimens taken from the operated animals, the liability to serious consequences of such a course.

A paper by Dr. Doyen, of Paris, "On the Surgery of the Stomach," was read by title.

Intestinal Anastomosis.—Dr. Martin y Gil, of Malaga, presented a communication on discs of ivory deprived of their lime salts as a mechanical help for intestinal anastomosis. He exhibited the discs and explained their advantages in the matter of flexibility and absorbability.

Dr. Frank, of Chicago, then presented a paper on his new absorbable intestinal coupler.

Sarcoma of the Omentum.—Dr. Djemil Pasha, of Constantinople, reported a case of sarcoma of the great omentum and of the transverse colon, the consequence of a silk suture left in the stump of the epiploon during the course of an operation for the radical cure of inguinal hernia. The operation wound closed by first intention and the patient left the clinic the eleventh day after the operation, perfectly cured. Two months later he began to have intestinal symptoms, some digestive troubles, and pains around the umbilicus. The symptoms of occlusion of the intestine supervened, and at the laparotomy a tumor was removed, which was found on microscopical examination to be a sarcoma. This was the second time in his practice that the speaker had seen a tumor develop when a silk ligature had been left in the tissues. He thought that while the development of the tumor might be due to the accumulated irritation of the presence of the foreign body on tissues predisposed to the embryonal overgrowth, it was much more probable that the sarcoma was due to the presence of a micro-organism and that the sterilization of the silk even at a temperature of 140° C. was not complete. The microbe of sarcoma resists the sterilizing process, and afterward excites neoplastic formation.

Splenectomy.—Dr. Thomas Joannescu, of Bucharest, read a paper on this subject. He reported the removal of the spleen twelve times—eleven times for ague cake, once for hydatid cysts. He had never found that any disadvantages accrued from such removal, but said that, on the contrary, the patient's general condition improves almost immediately. There is an almost immediate increase in the number of red blood corpuscles, sometimes preceded by a short interval of diminution. The malarial cachexia becomes less marked, probably owing to the fact that, as Laveran has shown, the spleen is the favorite haunt of the malarial organism and that it is from there that it sallies from time to time, and that this source of constant reinfection is removed. The speaker stated also that the urotoxic coefficient is lessened after the removal of the spleen to a distinctly noticeable degree, and he regarded the law of urinary hypotoxicity as established for asplenic subjects, whether the spleen has been surgically removed or its function has been lessened by disease and degeneration. Neither the size of the spleen nor the age of the subject constitutes a contra-indication to splenectomy. Dr. Joannescu regarded the inefficacy of medical treatment continued for a long time as an all-sufficient indication for splenectomy. When to this are added pain, discomfort, and commencing malarial cachexia, then the indications are absolute. In all cases the operation is followed by immediate improvement in the general condition. In fifteen cases of splenectomy there were three deaths, a mortality of 15.4 per cent.

Second Day—Saturday, August 21st.

Cancerous Strictures of the Digestive Tract.—Dr. Czerny, of Heidelberg, read a paper entitled "Therapy of Carcinomatous Strictures of the Œsophagus, Pylorus, and Rectum, with the Success of Various Methods of Treatment." He considered cancer of the œsophagus above the thorax perfectly amenable to surgical treatment, either radical or palliative, according to the extent of tissue involvement. As to intrathoracic œsophageal cancer, the question was very different. Attempts at removal were so dangerous that he considered the operation almost unjustifiable, although by the posterior route the operation

might be feasible. The improvement of its technique is one of the problems for younger surgeons to solve. Dilatation of strictures by means of bougies is of the greatest use in cases in which nutrition is interfered with by the impossibility of swallowing. He had seen a case go on for years under the use of bougies, when the malignant growth was not rapid, that would have been fatal from inanition without them. The œsophageal *sonde à demeure* might have its indications; the speaker had had no experience with it. When methods of dilatation fail to make alimentation possible in the ordinary way, he considered gastrostomy a legitimate resource. The making of a valvular opening by which the muscles of the abdominal wall are used to form a sort of sphincter is especially commendable. In cases of cancer of the pylorus, the main difficulty is one of early and positive diagnosis. It is only when all the classical symptoms are present that the surgeon is justified in operating. There are many surgeons who can report patients living from four to six years after the resection of the pylorus for cancerous infiltration. When resection is not possible, owing to the size of the tumor, or when the contraindication of enlarged glands or adhesions of the pancreas exists, then gastro-enterostomy is our only resource. It spares the patient, restores his digestive functions, and lengthens his life by decreasing the irritation of the cancerous mass. For gastro-enterostomy the Murphy button is extremely commendable. The speaker had himself used it in fifty-six cases. It very materially shortens the time of operation, which is an important item for the run-down, poorly nourished patients who come for such operations; it thus shortens the time of anæsthesia—another important item; it is just as sure when carefully and properly employed as the most complicated suture method, and it enables us to feed the patient sooner and with less risk after the operation than by any suture method. Besides this, there seems to be less tendency to stricture after the use of the button than with suture methods. Professor Czerny had noted this himself in two patients on whom the operation had been done three years before death. The treatment of rectal carcinoma is extremely encouraging, and is growing more and more so as our methods of diagnosis and operation improve. The speaker had one patient alive twelve years after an operation for rectal carcinoma, and another seven years after. Many reports of cured cases of rectal cancer are being made. A recent set of statistics has given the recurrences as about sixty per cent., but rectal carcinoma recurs sometimes very late. Czerny had known of two cases in which the recurrence had taken place more than twelve years and eight years respectively after operation, so that it is hard to say of how much real value statistics of cures may be. When rectal carcinoma is inoperable, then the formation of an artificial anus becomes the surgeon's duty, as in the corresponding case of the pylorus. It saves the patient pain, helps his general nutrition, removes irritation of cancerous elements, and so lengthens the patient's life.

Dr. Ceccherelli, of Parma, read a paper on the same subject. In cases of stricture of the œsophageal opening, he employed a special method, which fulfils the three important conditions of giving support to the stomach, making a valve for the opening, and forming this opening at a distance from the pyloric end. For pyloric strictures he believes that pyloroplasty is indicated when there exists a fibrous ring. In ulcers of the stomach gastro-enterostomy is useful and is more definitely indicated than resection, except in cases in which the ulcer is surely single and does not extend into the pylorus. He had made a special study of what are called syphilitic strictures of the rectum, and had shown histologically that syphilis is the original cause, but that an ordinary chronic inflammatory process supervenes and constitutes the morbid after-condition. On this, of course, syphilitic treatment has no effect, and the stricture must be dilated or treated radically with the knife.

Local Anæsthesia in Abdominal Operations.—Dr. I. E. Van Iterson, of Leyden, followed with a communication on the same subject. The main feature of his paper was the fact that all of the speaker's intestinal operations were accomplished without general anæsthesia. Of these there were sixteen gastrostomies, twenty gastro-enterostomies, two resections of the pylorus (one patient still living and well sixteen months after the operation), one jejunostomy, and ten colostomies. His plan is to inject two syringefuls of one-per-cent. solution of cocaine into the abdominal wall; this makes the external incision painless. Manipulation of the intestine causes no complaint on the part of the patient, unless the mesentery is pulled on. The stitches can be inserted into the abdominal walls after the operation without causing much pain, thanks to the persistent effect of the cocaine injections. The advantages of the method are that the exhausting effect of the long anæsthesia on patients who are already weakened by inanition is avoided. Besides, the giving of food may be begun at once. While the patients are still on the table, Dr. Iterson begins to give small quantities of milk, and this is continued every half-hour afterward. Another feature of this paper was the statement that the author usually has his patients sit up during the convalescence after the operation, and has their position frequently changed. He thus avoids the hypostatic pneumonias that so often carry off weakened patients after serious operations. Neither the operating without general anæsthesia nor the changes of position afterward are ungrateful to the patients, who seem very well satisfied with the methods employed.

Dr. Sematzky, of St. Petersburg, in a paper on the methods of gastro-enterostomy in strictures of the pylorus, said that in the ordinary method of making gastro-enterostomies the bile and pancreatic fluid would be conducted into the stomach and inevitably lead to nausea and vomiting. This was a great defect in the present methods. After a series of experiments on dogs, he had devised a method by which the presence of bile in the stomach may be avoided. He makes a transverse resection of the lower end of the jejunum and unites the lower section to the stomach; the upper part is joined by an anastomosis with the small intestine, twelve to sixteen centimetres lower. This allows the pancreatic secretion and bile to find their way properly into the intestine, but not into the stomach.

The Vaginal Route for Rectal Operations.—Dr. Heidenreich, of Nancy, read a paper on "The Vaginal Route in the Resection of the Rectum," in which he advocated an operation through the posterior vaginal wall in all cases of carcinoma of the rectum in women. The operation is not so serious or so bloody as that known as Kraske's. In the case of smaller tumors the operation commends itself by its extreme simplicity; in that of large tumors it gives the most room for operation; and when tumors are situated high up in the rectum it enables the operator to get at them better than any other way. The external sphincter can be easily and completely preserved, and incontinence is thereby avoided.

Treatment of Ischuria following Hypertrophy of the Prostate.—Dr. Bottini, of Pavia, in a paper on this subject, demonstrated his new method of dealing with these cases. His instrument resembles a lithotrite. The movable parts can be used as a galvano-cautery for burning a groove through the prostate. The current is supplied by a specially made battery, and the strength of the current is entirely under the control of the operator. After the blades of the instru-

ment have been inserted in the prostatic urethra, they may be turned in the direction necessary to destroy that portion of the prostate which seems to offer the greatest obstruction to the passage of urine. The results of the method are excellent. Within a few days, sometimes hours, the patient urinates voluntarily. In ten days all catheterization can be stopped. The relief afforded, according to the author's claim, is complete and permanent. The instrument may be employed after local anæsthesia by cocaine. It obviates the dangers which have so far attached to all surgical attempts to re-establish the urethral canal through the prostate, especially doing away with the liability to hemorrhages. The cautery acts effectively in closing all blood-vessels. A current of ice-cold water flowing through the instrument effectually protects healthy tissue. The contraction of the resultant cicatrix is never sufficient, when the cauterization has been thorough, to bring back the old symptoms of prostatism. Surgeons from other lands, among them Freudenberg, of Berlin, and Kümmel, of Hamburg, have employed the instrument successfully, and the reports of their cases show that it is not in its inventor's hands alone that the instrument is effective.

Third Day—Monday, August 23d.

Treatment of Infected Wounds.—Dr. E. Braatz, of Königsberg, read a paper on this subject. Infected wounds, he said, must be treated on strict antiseptic principles, and in successive dressings every care must be taken that instruments and everything else that comes in contact with the wound are thoroughly sterilized. One infection may be followed by another of severer character, and this mixed infection often runs a severe course.

Dr. Le Dentu, of Paris, read a paper on the same subject, in which he advocated the use of some of the newer antiseptics in preference to sublimate solutions.

Silver as an Antiseptic.—Dr. Credé, of Dresden, read a paper containing an interesting report on his method of treating wounds with silver, which, after an application of nearly two years with a considerable number of patients, has proved to be most successful. Although admitting all the advantages of asepsis, he said that it was of limited application and was impracticable for the physician who had no modern hospital at his disposal. Credé's method is based upon the antiseptic value of the lactate and the citrate of silver and their non-toxic properties. Experiments made with the internal exhibition of silver salts showed that they possess a certain power as general antiseptics, but for the purpose of a general disinfection only metallic silver can be used, and this, of course, in a condition which allows it to dissolve in water and albuminous fluids. The speaker believed that he had discovered in soluble metallic silver a remedy which is able to disinfect the whole of the body, and which represents a specific against septic infections, in so far as these have not caused organic lesions.

Permanence of the Results in the Radical Cure for Hernia. Dr. Lucas-Championnière, of Paris, read a communication with this title. In seventeen years he had had more than six hundred cases of radical operation for hernia, and so believed himself in a position to formulate some practical conclusions. It is the rule for a hernia after a good operation not to relapse, even when no support is worn. Any operation that does not penetrate the abdomen and leaves intact the contents of the inguinal canal and the canal itself must be considered as absolutely without value. Operations limited to the external orifice of the canal are not radical cures in the true sense. After the operation the abdominal wall should be submitted to regular and methodical movements, and the patient should avoid as far as possible growing very stout after the operation. The fattening of the subject is one of the chief causes which lead to relapses by a fatty infiltration of the muscles of the abdominal wall. Gradual progression in the taking of exercise after an operation for radical cure is a point of the highest importance in obtaining a definite solidity of structure in the wall, which will afford the necessary resistance for violent exercises. The bicycle is eminently suited to this purpose. In the speaker's experience relapses have always come from one of two causes, namely, the excessive taking on of fat or sudden violent efforts, as in lifting.

The Suture of Large Vessels in Continuity.—Dr. J. B. Murphy, of Chicago, read a paper on this subject, in which he described the experiments already detailed in the Medical Record,[1] and gave the details of two unreported cases and demonstrated his method of performing the operation and his instruments for it. Communications in English are usually received with brutal discourtesy at international congresses; this, however, did not share the usual fate, but was listened to with profound attention. The more remarkable of the two cases was one of gunshot wound of the subclavian, in which, after cutting down on the huge hæmatoma which had formed in the four days since the accident and securing the artery, Dr. Murphy resected three-fifths of an inch of the artery in its second portion, sutured it, and had immediate return of pulsation at the wrist. The paper excited the greatest interest, and the instruments were the subjects of marked attention and discussion at the close of the session.

The Radical Treatment of Hernia.—Dr. Cazin, of Paris, read a paper, the joint work of himself and Professor Duplay, on a new method of treating the sac in the radical cure of inguinal hernia. The method has two essentials: 1, The sac is preserved and is used for the purpose of making a solid cicatrix, forming a sort of organized stopper between the peritoneum and the transversalis fascia; 2, buried sutures are dispensed with, and this the authors consider a decided advantage when it can be done without compromising the solidity of the cicatrix. For suturing the walls of the hernial opening, they employ silver wire, which is removed on the sixth day. The operation is not suitable for all classes of hernia, for when there is a large opening into the canal some procedure like Bassini's must be employed for the reconstruction of the abdominal walls, and then buried sutures must be employed. The abandonment of buried sutures they consider a decided advantage, for when of silk these often give rise to late infections which are exceedingly troublesome; when of catgut they are sometimes absorbed so readily that they do not remain long enough to serve for the formation of a firm cicatrix. The authors had operated upon thirty-three cases in two years with their method. The cure was without incident in all cases, and the relief afforded seemed to be permanent.

Dr. Corbin, of Jassy, read for himself and Dr. Vicol a report on two hundred operations for the radical cure of hernia done in the hospital of the fourth French army corps. Of these, one hundred and ninety-eight were inguinal hernias, one was crural, another umbilical. The number of patients operated on was one hundred and ninety. In most of the inguinal hernias the procedure employed was that of Lucas-Championnière. All of the patients survived the operation, and in but twenty-one was there elevation of temperature after the operation. In three cases there was some deep suppuration. Since the operations there had been relapses in twelve cases. All of them occurred as a consequence of the heavy work the men

[1] Vol. li., p. 73.

had to engage in after leaving the hospital, and in nearly all the relapses there is a history of a special violent effort made at the time of the recurrence of the hernia.

Treatment of Spinal Deformity.—Dr. Calot, of Berck-sur-Mer, read a paper on the treatment of the deformity of Pott's disease. He became tired some time ago of treating Pott's disease in the way usually recommended, by absolute rest and fixation of the parts. Seeing the deformity increase and the prominence become more pronounced, despite the presence of a corset or jacket or other fixation apparatus, he looked around for another mode of treatment. Instead of being merely passive, he adopted active measures. He applied pressure to the prominence while extension was made. Having caused the hump to disappear, he fixed the patient in the position of correction by a carefully applied plaster jacket, which was retained or replaced by a similar one until the tuberculous process had ceased. This usually takes months; it may take a year or more. The important part of the process is the correction of the deformity, which is done gently and carefully, but with sufficient force to secure absolute correction. The indications for this correction are twofold: First, it separates the diseased portions of the vertebræ and fixes them in that position so that they fail to be continual sources of irritation to each other. The second is the lessening of the final deformity of the case. The speaker did not claim that the intervals between the bodies of the vertebræ will be filled up by new bone, yet during the process of healing there is undoubtedly an adaptation of bony structures that retains the spinal column in its corrected position. The treatment is especially suitable for recent cases of Pott's disease, though it may be applied with due circumspection to older cases.

Dr. Joannescu, of Bucharest, presented a paper advocating the reduction of the deformity of Pott's disease by pressure at a single operation. He reported thirteen cases treated during the past year, most of which had been exhibited before the Academy of Medicine in Bucharest. His attention had been called to the subject by Dr. Calot's reported cases, and it was Dr. Calot's method with certain modifications that he employed. He had abandoned traction by assistants, and substituted mechanical means. This dispenses with the need for so many assistants; the traction force is absolutely and methodically regulated; it is not applied by fits and starts, as is almost inevitable in manual traction; and finally, it may be continued not only during the process of reduction but also until the plaster jacket has been applied. With mechanical means the absolute minimum of force necessary to produce the reduction may be employed, which is not so easy when manual traction is used. In his method the child is placed face downward on two elevated cushions—the one under the upper part of the sternum, the other under the pelvis. Traction is applied through bandages, having their attachments so that the distance between pelvis and occiput is gradually increased. Then pressure is applied over the gibbosity until it is reduced. From forty to sixty kilograms of tractive force and forty to fifty kilograms of pressure are sufficient for even inveterate cases. Anæsthesia is necessary only during the period of reduction, and not during the putting on of the plaster jacket. The results of the procedure have been eminently satisfactory as compared with the old methods. The only immediate danger is from the anæsthesia, not from the manipulations. The administration of the anæsthetic should be stopped when reduction is complete, and in recent non-ankylosed cases may be dispensed with entirely.

Dr. Redard, of Paris, had tried Calot's method for the immediate reduction of the prominence of Pott's disease in thirteen old cases with ankylosis, and had not succeeded in effecting reduction after the employment of the maximum of pressure and traction that he thought safe. In recent cases he had succeeded in effecting reduction without much difficulty. Even when the deformity is quite large, provided it is not more than a year old, the manipulations are easy. In some cases even after two years the speaker had succeeded in effecting the reduction. Dr. Redard employed mechanical traction and mechanical pressure to accomplish his results, and considered them safer than direct manual force, because their amount can be exactly measured. He did not think the old methods should be entirely abandoned for the new.

The Fundamental Principles and Methods of the Treatment of Scoliosis.—Dr. Dolega, of Leipsic, read a paper on this subject. According to the generally accepted explanation of the etiology of scoliosis, the condition is a functional deformity of the vertebral column, due to the fact that certain muscles, either congenitally or from some lack of trophic influence, are not able to support the spine properly. When inveterate it is complicated by the fact that unequal pressure on different parts of the vertebræ has led to their uneven development. To prevent this and to correct the deformity while the patient is young, there are four indications: (1) General gymnastics in conjunction with massage for the improvement of general muscle tone. (2) Suspension, which relieves the overstrained muscles for a time and enables them to catch up in nutrition and tone. (3) Gradual reduction of the deformity by pressure, which puts the weaker muscles in a better position to act. (4) Retention of all that has been gained by suspension and corrective pressure by the wearing of an apparatus.

Staphylorrhaphy.—Dr. Le Dentu, of Paris, demonstrated certain instruments for use in staphylorrhaphy. Among them notably were a mouth gag with a crossbar, which rolls the tissues forward and brings the field of operation nearer to the surgeon; a specially constructed dissector with a curve in two directions, that enables it to be used to best advantage as regards the curve of the palate and the confined region in which it has to be manipulated; a needle holder with a concealed needle, that when pushed upon describes a curve that brings it toward the operator, and when withdrawn carries the ligature through the tissues.

Indications and Results of Lithotrity.—Dr. Albarran, of Paris, reviewed this subject as it concerns present-day practice. It used to be said that there were two contraindications, youth and extremely large stones, but these have disappeared before the march of modern surgery. Scarcely ever is it necessary to do a cutting operation for stone. It is the rarest exception to find stone in a patient too young for the performance of lithotrity. The difficulty used to be the introduction of instruments strong enough to be depended on into the urethras of young male patients, but this has disappeared before the gradual perfection of instruments. As to the size of stone, nothing is now too large for the lithotrite. He considers lithotrity one of the great triumphs of modern surgery—that this operation should have reached the perfection and universality of application that it has. Instead of a serious bloody operation with at least fourteen days or three weeks in bed in the most favorable cases, there is a simple surgical manipulation and the patient is able to be out of bed in three days and resume his occupation in six days.

Ischuria from Prostatic Hypertrophy.—Dr. Freudenberg, of Berlin, reviewed the various operations for difficult urination from prostatic hypertrophy. He regarded the Bottini method as the best. He reported a number of successful cases, one in which, after every-

thing possible had been done for the patient by the old methods, the prostatic urethra was enlarged by Bottini's electro-caustic method; he was able to urinate freely some hours afterward and fourteen days after the operation all catheterization was given up.

Dr. Bottini said that he had examined Dr. Freudenberg's modifications of his apparatus. They concerned especially the possibility of thoroughly asepticizing the instrument, and certain changes in the electrical connections and battery powers, and he considered them distinct improvements and recommended them to the profession.

Dr. Watson, of Boston, said that from his personal experience he did not think Bottini's apparatus applicable to all cases of prostatic hypertrophy. While it would be effective in the simpler cases of bar at the neck of the bladder, he hardly thought it would relieve the cases in which there was extreme prostatic hypertrophy. No amount of manipulative skill would enable one to direct the instrument so as always to come upon the offending prostatic hindrance.

Dr. Lavista, of Mexico, did not consider the Bottini procedure applicable to the cases of extremely large prostate. He thought that the relief afforded in such cases would be only temporary.

Catheterization of the Ureters.—Dr. Albarran, of Paris, read a paper on catheterization of the ureters in the male and female, and described a new instrument that greatly facilitates the manœuvre. With his apparatus he is able to introduce a rubber catheter supported by a sound of a calibre of No. 10 French. After the manœuvre has been repeated for some days a No. 13 or No. 14 may be introduced.

Lithotrity.—Dr. Herbert Milton, of Cairo, read a paper on this subject (see page 418).

Tumors of the Bladder.—Dr. Nitze, of Berlin, read a paper on the intravesical removal of tumors of the bladder. He described a new cystoscope for the employment of a snare under full light in the cystic cavity. Only benign tumors can be removed. For malignant tumors a more radical operation must be employed when operation is indicated. Small tumors that have for years been causing serious constitutional trouble from hemorrhage can be easily removed, and even reasonably large tumors can be removed piecemeal. In the speaker's experience this method has given much better results than *sectio alta*.

Dr. Watson, of Boston, asked to be allowed to correct the impression made by the paper of Dr. Albarran, that cutting operations for stone were the favorite procedures for vesical calculus in America. He was glad to see that French surgeons had so thoroughly taken up the rapid method invented by Bigelow and were carrying it out with such perfection.

Elephantiasis of the Testicle.—Dr. Le Dentu, of Paris, reported a case of elephantiasis of the testicle, hydrocele, lymphatic varicocele, and lymphangioma of the inguinal canal and of the pelvis due to the presence of filaria sanguinis hominis. The change of climate always arrests the progress of the filarial disease, he said, and he thought it probable that the use of electricity may be found to cause a retrograde process in the hypertrophied lymphatic tissues.

Pseudo-Cystitis.—Dr. Guépin, of Paris, for himself and Dr. Grandcourt, read a paper on this subject. They held that there is a series of diseases with bladder manifestations in which no pathological condition exists in the bladder. These have usually been diagnosed as cystitis, and it is only careful modern diagnosis that has differentiated them. The bladder symptoms in such cases are the result of nervous reflexes, principally from an affected posterior urethra, but they may also come from the anterior urethra, from the ureter, and even from the kidney. The result of the reflex nervous excitation brings on a congestion that aggravates the symptoms and makes the condition still more simulative of true cystitis. The diagnosis is often extremely difficult and depends finally on careful local examination. It is to be remembered that in cases of false cystitis the symptoms are always aggravated by intravesical medication.

Absorption by the Mucous Membrane of the Bladder.—Dr. Gerota, of Bucharest, showed by a series of microscopic plates that, while there was imbibition on the part of the mucous lining of the bladder, there was no real active absorption. Coloring matters were found to have penetrated between the cells, but they were not taken up by the lymphatics. Poisons such as strychnine might thus gradually and very slowly find their way into general circulation, but they were not really absorbed.

Spontaneous Fracture of Vesical Calculi.—Dr. Severeano, of Bucharest, reported a case of spontaneous fracture of a large calculus. He discussed the theories of the cause of the fracture, rejected the idea that it was due to active excessive contraction of the bladder walls, but thought it was much more probably due to the formation of carbonic acid within the calculous masses.

Prostatectomy.—Dr. Desmos, of Paris, read a paper on this subject. He regarded the hypogastric route the preferable one, as the surgeon has to grope less in the dark, can more readily diagnosticate the exact condition that causes the urinary difficulties, and is better able to judge what the indications for operation really are. In twenty-three prostatectomies he had successful results in thirteen, the patients recovering almost completely their urinary potency; in four cases there was distinct improvement in the urinary symptoms. In the midst of the new inventions for the relief of prostatism now so frequent, he believed that the old traditional procedures still had their place and that improved technique with modern methods made them often the operation of choice.

Fourth Day—Thursday, August 24th.

Gastric Operations.—Dr. Kader, of Breslau, read a communication on the operations on the stomach done in Mikulicz's clinic during the last fifteen years. There were seventy-one operations for non-malignant troubles of various kinds, with a mortality of 22.5 per cent. In all uncomplicated cases the mortality was but 8.4 per cent., while in uncomplicated cases of excision of gastric ulcers the mortality was but 4 per cent. In cases of carcinoma the total mortality was 21.6 per cent.; the mortality of uncomplicated cases was but 15.5 per cent. The mortality during the last two years had been a little higher than in that of the preceding thirteen years from 1882 to 1895, but this was due to the fact that much more complicated and difficult cases were now operated upon, and the circle of inoperable cases was constantly being narrowed.

Surgical Treatment of Graves' Disease.—Dr. Kocher, of Berne, read a report on his results in the surgical treatment of exophthalmic goitre. In all he had treated forty-three cases, which he divided into three classes: (1) strumæ vasculosæ; (2) atypical cases; (3) typical cases. In the six cases of vascular struma surgical interference by partial excisions and ligation of arteries had been uniformly successful. In sixteen atypical cases he had had thirteen complete cures and three improvements. In the typical cases he had operated in various ways. In three cases in which one-half the gland was removed, two were cured, one was improved. In three cases of ligature of the superior and inferior thyroid arteries on one side, two were cured, one was improved. In five cases in which two arteries on one side and one on the other were tied, four were cured, one was improved. In three cases in

which all four arteries were tied, two cases were cured and one proved fatal. The author formulated the following conclusions: (1) Graves' disease is due to hyperplasia of the thyroid and excessive function with presence of too much of its secretion in the system. (2) In the early stage of the disease it is possible to relieve it by surgical treatment. (3) The surgical treatment must be different for different cases, but the best method in general seems to be the removal of one-half the gland and the ligature of one artery on the other side. The operation is not an easy one, so that it will perhaps be best as a rule to excise the smaller half. It is in the early stage that the disease is especially benefited by surgical treatment, and it is consequently in this stage that the disease must be claimed as a surgical affection and come at once into the surgeon's hands.

Resection of the Cervical Sympathetic.—Dr. Thomas Joannescu, of Bucharest, read a paper entitled "Total and Bilateral Resection of the Cervical Sympathetic." He reported three cases of removal of the whole of the cervical sympathetic for exophthalmic goitre. The results were excellent. The exophthalmos completely disappeared and the other symptoms of the disease were almost if not entirely relieved. In twenty-eight cases of epilepsy he had also divided the cervical sympathetic and with excellent results. In fact, for epilepsy and exophthalmic goitre he regarded the total bilateral section of the cervical sympathetic as the only rational surgical interference. The immediate fatality of the operation ought in good hands to be absolutely nil. No after-effects that will inconvenience the patient are to be expected. As the possibility of resecting all three ganglions of the cervical sympathetic had been questioned, he exhibited the series removed by himself and preserved in alcohol.

Subcutaneous Extirpation of Lymphatic Glands.—Dr. Dollinger, of Budapest, read a communication entitled "Further Experiences with the Subcutaneous Extirpation of Tuberculous Lymph Glands in the Throat, Neck, and Submaxillary Region." He had employed in a variety of cases and with excellent results the subcutaneous method he described some time ago. With care the danger is no greater than with the open method and the resulting scar is so much less that patients readily consent to the operation. The greatest surgical cleanliness is absolutely necessary.

Harelip.—Dr. Severeano, of Bucharest, described his operation for this deformity. He splits the sides of the fissure into two portions, a mucous and a cutaneous one, and brings them together by separate sets of sutures. He thus avoids the loss of substance necessitated by the freshening process in all the other harelip procedures, and as the flaps to be brought together are thinner he secures more close coaptation and so lessens the prominence of the resulting cicatrix.

The evening session on this day was held in union with the section in neurology.

Brain Surgery.—Dr. Bergmann, of Berlin, read a paper on the surgical treatment of brain tumors. He reviewed the history of brain surgery and cerebral localization. Great as has been the progress, there still remains much to do. Diagnostic methods are still not sure enough to guard the surgeon against error. He had himself opened the skull for tumor without finding one. Such is now the perfection of surgical methods as regards asepsis, however, that in case of doubt a trepanation for diagnostic purposes in serious cases is justifiable. In about one out of ten cases operated on for tumor no tumor is found, and in one out of six cases operated upon, though the tumor has given definite symptoms of localization, its removal is impossible. Though he had spoken lightly of the operation, he would not be understood as denying its grave dangers, not alone during the operation itself and immediately after, but remotely from the pressure of the resulting cicatrix causing epilepsy.

Dr. Auguste Voisin, of Paris, reported a case of Jacksonian epilepsy treated successfully by craniectomy. The case was that of a young man of seventeen affected since the age of four with convulsive attacks beginning with a painful aura in the left arm. The number of attacks had become so frequent that he was unable to leave his bed. At Dr. Voisin's request Dr. Péan made a large craniectomy over the fronto-parietal ascending convolutions. The dura was found depressed, the pia was hyperæmic, the brain tissue seemed to be sclerotic. The result was eminently satisfactory. All pain in the left arm has disappeared, though there still occur at times certain slight involuntary twitchings. The patient has completely recovered his intelligence and his general health, and has gone back to work. It is now two and a half years since the operation. The patient has had but three attacks since the operation.

Dr. J. Lucas-Championnière, of Paris, read a paper on the same subject. He had done sixty-six trephining operations for non-traumatic cerebral lesions, or lesions of traumatic origin but very old, and twenty for fracture of the skull. He thought the cases of Jacksonian epilepsy with an absolutely localized lesion not very common. When definite lesions are found there are always, in Dr. Championnière's experience, besides the localized convulsions, localized paralyses, or contractures. These are in fact the best directing symptoms the surgeon can have. In cases of operation for epilepsy one must avoid having too narrow an operative field, for otherwise one runs the risk not alone of not finding anything but also of bringing no relief to the patient.

The Failures in Brain Surgery because of Faulty Diagnosis.—Dr. Oppenheim, of Berlin, read a communication with this title. He thought that the great desideratum now in brain surgery is not a better method of operation but more assured diagnosis. Brain localization is often most doubtful; the diagnosis of brain abscess from brain tumor is often almost if not quite impossible, yet a surgical operation for the one or the other condition is quite a different matter as regards immediate and remote results. Pressure symptoms are often deceitful, and a condition of cerebral poliomyelitis may simulate in all respects the localization symptoms of a tumor. It may be impossible even to diagnose the hemisphere in which the lesion exists, and reports of paralysis with the lesion on the same side of the brain are growing more frequent. The pressure against the skull on one side owing to the pathological condition present may by a sort of contrecoup be manifested more on the other side of the brain, either because the pressure is exerted more directly on the motor regions on the other side, or because of nutritional conditions or idiosyncrasy. Then a lesion on one side may be complicated by hydrocephalus on the other side. Finally the peripheral symptoms may be deceptive.

Dr. Doyen, of Paris, exhibited a set of instruments for the rapid opening of the cranium. They consist of a special boring machine with which the diploe is penetrated and then perforated with an olive-pointed tool, thus avoiding all danger of wounding the dura even when there are extreme irregularities of the cranial vault. He makes several apertures and then connects them by means of a saw making one thousand revolutions a minute, run by electricity and protected from injuring the brain or membranes by a metal director.

Dr. Bruns, of Hanover, read a paper on "Some

Specially Weighty and Practically Important Diagnostic Points in the Differential Diagnosis and Localization of Brain Tumors." The most difficult differential diagnosis is that between tumors of the frontal lobes and of the cerebellum. 1. Disturbances of equilibrium may occur in both, and so mistakes of diagnosis may easily be made as to tumors having their seats in either of these locations. Careful consideration of symptoms makes a differential diagnosis possible, owing to important special symptoms that occur with frontal tumors. 2. Homonymous hemianopsia is of little weight for differential diagnosis. When right-sided homonymous hemianopsia with alexia and optic aphasia is present from the beginning, we may conclude as to the presence of a tumor in the white matter of the left posterior lobes. 3. Tumors in the neighborhood of the central convolutions, especially in the frontal and parietal convolutions, on account of the pressure symptoms, often cannot be diagnosed from tumors of the central convolutions themselves. 4. The percussion signs and the sensitiveness of the skull with the presence of tympany or cracked-pot sound, when it is demonstrable with certainty and facility, are of the greatest importance for localizing diagnosis of tumors. Especially is this true when the percussion symptoms accord in their indications with the localizing general symptoms. In the difficult cases of differential diagnosis of the central convolutions and their immediate neighborhood evident percussion symptoms and localized tenderness may make a final and absolutely certain diagnosis possible. In these cases the percussion symptoms are much more significant than the localizing brain symptoms. Unfortunately these percussion symptoms and sensitiveness occur only when the tumor is very superficially located.

Dr. Lavista, of Mexico, read a paper on the results of surgical intervention for Jacksonian epilepsy and the necessity for its early employment. The efforts of surgeons to relieve cerebral disorders are satisfactory neither to themselves nor to the neurologists; he could not believe that the centres and regions of the cerebral cortex were definitely limited. They represent only the regions where there is the maximum of nerve force for a particular purpose. Besides, we know nothing of the superior and middle frontal convolutions. Notwithstanding a lack of exact knowledge as to localizing symptoms, however, the surgeon is tempted to interfere because otherwise the course of the disease is so hopeless. Our only resource under the circumstances then is a large opening in the skull at the time of operation, so that we may examine as much of the cortex as possible. In this way one is often able to find lesions in parts where no localizing symptoms could be expected. One thing more must the surgeon bear in mind in operations for Jacksonian epilepsy, and that is that the sooner the operation is done the better. The brain tissues acquire a habit or degenerate, and then operations do not give satisfactory results.

Dr. A. d'Antona, of Naples, read a paper on the remote results of operations for partial and general epilepsy. He believed that the remote results would justify the operation for Jackonsian epilepsy, though perhaps not that for general epilepsy. He wished to protest against the teaching that an exploratory trepanation was ever justifiable. He said the use of very large openings for diagnostic purposes was not to be thought of.

Dr. Joannescu, of Bucharest, presented a communication on temporary hemicraniectomy. He believed that with the present uncertain state of cerebral diagnosis and the absolute freedom from risk of aseptic surgery, a large opening in the skull was the only one that a surgeon should make. He did not agree with d'Antona in his condemnation of large openings, because, while it might seem conservative, it was really quite as risky to make a small opening as a large one, and in the latter event the chances of doing good were greatly increased.

Dr. Kocher, of Berne, read a paper on the traumatic origin of Jacksonian epilepsy and its non-occurrence after surgical interference. He had had in the last ten years eighteen cases of complicated skull fractures which had been carefully treated surgically, but in which there must have followed the formation of extensive cicatrices. All of them had been carefully followed and in none had there been any epilepsy. There would seem to be some other cause necessary besides the mere presence of a scar to account for the epilepsy.

BRITISH MEDICAL ASSOCIATION.

Sixty-Fifth Annual Meeting, Held at Montreal, Canada, August 31, September 1, 2, 3, 1897.

(Special Report for the Medical Record.)

SECTION IN SURGERY.

(Continued from page 430.)

First Day—Wednesday, September 1st.

The Accurate Measurements of Spinal Curvature.—Mr. R. Tait McKenzie read a paper with this title, in which he stated that the points to be noted in studying this disease were the difference in level of the shoulders, of the points of the scapulæ, and of the iliac crests, the deviation of the spinous processes at all levels, and a general outline of the hips and shoulders. We should also find the amount and show the nature of the rotation. He referred to many plans or devices for measuring the deformities. Mr. Bernard Roth had an ingenious device, consisting of a plate of pure tin with which diagrams were made. He preferred a device of his own, which consisted of a fixed horizontal iron stand into which a rigid upright rod is screwed firmly. To this rod two arms are attached by collars that can be moved up and down or clamped by thumbscrews. The lower arm passes behind the patient and clamps the hips, preventing any side movement. The upper arm passes in front of the patient and fixes the shoulders. To the collar of the upper arm is attached by a hinge a plate, to which a pantograph is screwed, set so as to make a tracing reduced to one in four. The paper, which is stretched over this plate and held by clips behind, is ruled in eight-inch squares. Hence a line passing vertically through eight squares or one inch would represent a distance of four inches covered by the pointer tracing the deformity.

Mr. Christopher Heath, of London, said that instruments had been used in the most reckless way, and were not only of no value but did positive injury. He had the opportunity of observing many of these cases treated by muscular exercises, and found that they had done well.

Dr. Gibney, of New York, said that until he had noticed Mr. Roth's method, he used to employ apparatus for the treatment of lateral curvature, but since that time he had almost entirely given it up and found that his successes were infinitely better. He found one or two difficulties in carrying out the method. One was the difficulty of keeping up the patient's interest in the gymnastics under the supervision of the speaker himself or his assistant, the friends maintaining that these exercises could be done as well at home. He still used the instruments in cases of stu-

pid girls who absolutely could not be compelled to carry out the serious treatment of their cases. He thought Dr. McKenzie's apparatus for tracing the best he had seen and that Mr. Roth's results were very satisfactory. He was very much impressed when in England with the amount of pain complained of by patients suffering from lateral curvature. This was not the case in the United States. Perhaps the reason of this was that the cases he saw here, being chiefly among the poor, were more inured to pain than the cases (mostly among the well-to-do) which he saw in England.

Dr. Ketch, of New York, said that he had made an analysis of two hundred and twenty-nine cases. Fifty-two were cases of deformity which had existed before the fifth year. He claimed that much better results could be obtained if cases could be seen early. He said it was very difficult to get patients to carry out the instructions regarding the exercises. The cases of lateral curvature divided themselves into two classes, namely, those in which the extrinsic muscles were affected, and those in which the intrinsic muscles were affected. In the first class there was usually no irritation and there was little difficulty in carrying out the treatment. Those in the second class were very troublesome to treat.

Dr. Lee, of Philadelphia, said that an early diagnosis should be made in these cases of lateral curvature. He had found that the lumbar region was the first affected. If the deformity is allowed to go on until the dorsal region is involved, perfect results cannot be hoped for. He fully concurred with Mr. Roth as to the value of exercise and posture in these cases.

Second Day—Thursday, September 2d.

Gunshot Wound of the Spinal Cord.—Dr. George A. Peters, of Toronto, then followed with a paper on this subject. He stated that the causes of death in such cases are shock, hemorrhage, and septic processes, while the factor which most largely determined the rate of mortality is the proximity of the cord lesion to the brain. Cases of this nature in civil practice are very infrequent. Although there have been cases in which after complete transverse lesion of the cord at various levels, the individuals have survived for periods varying from one to twenty-six years, yet it may be stated as a rule to which the exceptions are few that patients with such lesions die within a year of the injury. The determining causes of death are inflammation of the bladder and its sequelæ, bedsores and other trophic lesions, pyæmia, amyloid disease, and exhaustion. The speaker recommended median cystotomy as a routine practice in cases of this injury in male subjects, to imitate the short and straight urethra of the female, as the latter seems to suffer less from bladder symptoms. Dr. Peters then referred to the difference between the deep or tendon reflexes which are permanently lost in complete transverse lesions of the cord, and the superficial or skin reflexes which, as in a case narrated by him, may not only return but may even become exaggerated. The speaker believed that in the case of the skin reflexes the reflex arc remains intact and the exaggeration is accounted for by the overflow of sensation into motor regions in the cord, which are relieved of the natural inhibitory influence of the higher centres by the lesion; while in the case of the tendon reflex an influence is normally transmitted to the muscles to maintain their tone which is also interrupted by the lesion—hence the permanent loss.

The Advantages of the Absorbable Suture, Buried in Aseptic Wounds.—Dr. Henry O. Marcy, of Boston, read a paper on the suturing of wounds. He said that in a large minority of operative wounds made in healthy structures suppuration in some degree still occurs. The surgical technique is complete for making a wound aseptic, but the difficulty is in maintaining it in this condition. The cause of this is definite, viz., an open wound. The remedy is equally definite: "Hermetically close the wound and seal at the time of operation without drainage." The drainage tube was then discussed with disapproval. The most usual source of operative infection, he said, comes from the surgeon's own hands. Careful hand disinfection is of much greater value to the patient than a marble hall for an operative amphitheatre. The speaker then discussed the varieties of suture material, and stated as his opinion that all aseptic wounds should be closed by absorbable sutures under the most careful of aseptic conditions and that subcuticular sutures should be used for the coaptation of the skin. The carefully disinfected skin should be dried, the edges carefully coaptated and sealed with iodoform collodion, reinforced by a few fibres of absorbent cotton. Dr. Marcy condemned catgut, not so much because of its difficulty of sterilization, as of its inherent defects, a large share of its strength resulting from its being twisted and kept dry; when wet it is elastic, unreliable in knotting, and untrustworthy. Before twisting and drying it is a very thin flat band of connective tissue, the fibres of which cross obliquely, and is not unlike a very delicate silk fabric cut upon the bias. The advantages to be obtained from the use of connective tissue as a suture material are apparent, not only because it is absorbable, but because it is first surrounded by leucocytes, which little by little invade the suture. As absorptions go on, these cells are changed into connective-tissue corpuscles, and the suture material is thus more or less completely replaced by a living band of connective tissue. Formerly Dr. Marcy used tendons from the moose and caribou, but subsequently convinced himself that the tendons taken from the tail of the kangaroo were greatly to be preferred, since they are smooth, even, in any variety of size, have never been subjected to decomposition, and are therefore much less difficult of sterilization, while in strength they exceed any other animal structure. When properly chromicized they hold in the tissues about three months.

Coaptation and fixation at rest, with as little force as possible, of like structures, are the aim of suturing. Suture material more than required to secure this purpose is detrimental. The interrupted suture is faulty in that it holds at only the single points of insertion, and each stitch, moreover, requires a knot which is slow of absorption. The continuous suture requires but a single knot, and undue constriction is less liable since a compensation occurs, equalizing the force applied to the entire suture. Like structures as far as possible should be joined, fascia to fascia, muscle to muscle, etc. When coaptation has been accurate there are no pockets left for the retention of fluids, and as a consequence no drainage tube is required. As a rule, fatty structures should not be sutured, since aseptic fat necrosis not seldom results. Coaptation of these fatty structures follows the fixation of the muscles, fascia, and skin. The over-and-over glover's stitch is faulty, in that it unduly constricts the inclosed tissues. The speaker applied the suture deeply from side to side; the needle is introduced parallel to the long axis of the wound, and hence it is called by him the "parallel suture." The needle is introduced exactly opposite to the point of emergence of the preceding stitch, and when it is drawn upon the surfaces are evenly coaptated, and the suture is deeply implanted in healthy tissues, crossing the wounded edges at right angles. The subcuticular suture is effected in precisely the same manner, and the wound is sealed.

Conclusions: An aseptic wound thus closed with buried aseptic tendon sutures will remain aseptic, and in well-vitalized srtuctures will be followed by primary union. No expensive and troublesome dressings are required. The subsequent nursing and care are very greatly diminished. The anxious foreboding of the surgeon "lest something go wrong with the wound" is avoided. No stitches are to be removed, reducing greatly the dread and anxiety of many patients. Safety is greatly enhanced and the period of convalescence is shortened. When the work has been done with care, often the resultant cicatrix is scarcely visible—a matter of much importance in some portions of the body.

Some operations hitherto impossible have been rendered feasible by the use of the buried absorbable suture, *e.g.*, the reconstruction and reformation of the inguinal canal in the male, upon which is dependent the cure of hernia. It was for the cure of hernia that Dr. Marcy first used buried animal sutures in 1870. He is now, he said, in his fourth hundred of hernia cases, and has obtained a permanent cure in over ninety per cent. of the entire number, without a single death.

In laparotomy the permanent closure of the abdominal wound, without subsequent hernia, is rendered almost certain by the use of aseptic tendon sutures.

Traumatic Aneurism of the Internal Maxillary Artery, Treated by Ligature of the Common Carotid.—Dr. Langley Brown reported a case of this kind. The patient was a man who had been kicked by a horse. He was semiconscious on admission to the hospital, perhaps suffering from shock, and bleeding profusely from his right cheek, right ear, nose, and scalp. The right side of his face was much swollen, the right eye being completely closed, and the swelling extended half-way down the neck. The lower jaw was found to be fractured on the left side close to the symphysis, and on the right side through the neck of the jaw. Crepitation was also detected over the right malar bone. The temperature rose to 100.2° F. The next evening it fell to normal, and remained so until about the eighth day, when it registered 101.8° F., and five days later 104.6° F. During the next three days the swelling slightly decreased. On December 5th the temperature rose again and fluctuation was detected in the neck, from which six ounces of pus was evacuated through incision. On the thirteenth day a copious hemorrhage took place from the incision. The swelling now increased and on the 15th distinct pulsation was detected on the right cheek. On examining the mouth the soft palate was seen to be greatly depressed on the right side and congested, and pulsation was easily felt. On the 24th he had slight hemorrhage from the mouth, and on the 26th a more copious hemorrhage. Mr. Brown decided to ligature the carotid. On the third day after the operation the patient passed fæces involuntarily, but since that time he has had perfect control and made an uninterrupted recovery.

Umbilical and Epigastric Hernia. — Dr. A. S. Garrow, of Montreal, reported a case of this kind. He had found but one similar case on record. In this case the contents of the supra-umbilical protrusion consisted of large and small intestines, cæcum, with appendix and omentum, the latter being spread out so as to form a more or less complete sac. There were adhesions, and the hernia could be reduced only with difficulty. The umbilical hernia was small, sausage shaped, and contained but a single loop of small intestine, which was not adherent and was very readily reduced. The lesson he had learned from the case was that as in such cases it was impossible to recognize the double protrusion before incision, after opening the main sac and replacing its contents, a careful search should be made from within to determine whether any other hernia existed, before proceeding to remove the adipose tissue. The speaker's case was that of a woman who had been married twenty-one years, and had had three children. Some months after the birth of the third child, a small lump made its appearance about one inch above the umbilicus. This gradually increased in size until three years ago, and since then had grown rapidly. The principal symptoms were abdominal pain, a dragging-down sensation, and later disturbances in digestion. The tumor was irregularly hemispherical, freely movable, soft and doughy in some parts, but tense and elastic in others, irreducible, distinctly lobulated, somewhat tender on pressure, and palpation occasionally elicited gurgling sounds. The tissues above the part were very thin, so that the outline of the contents could be readily distinguished. By an elliptical incision the sac was reached and opened at its upper and left side. The contents were with difficulty disentangled, and reduction could not be effected until the opening had been enlarged upward about one and one-half inches, and then only with difficulty. On lifting up the mass preparatory to moving it, a gurgling sensation was detected, and upon dissection toward the middle line about two inches below the lower border of the upper opening, another sac, one and one-half inches in diameter and about three and one-half inches in length, was discovered, which on being opened was found to contain small intestines, was not adherent, and was readily reduced. The edges of both openings were freshed and brought together by stout catgut sutures. The patient made a good recovery.

The Operative Treatment of High Cancer of the Rectum.—Dr. James Bell, of Montreal, opened the discussion on this subject. It is only twelve years, he said, since the removal of diseased middle and upper portions of the rectum has become practicable through the introduction of Kraske's operation. As to the frequency of this disease, Mr. Sutton says that of every one hundred cases of carcinoma of the intestine, seventy-five occur in the rectum. The same rule applies here as in cases of cancer of the breast, that early and complete removal of the growth and of the contiguous glands has made possible many cases of cure. In no case had the speaker seen an absence of involvement of the glands. The reason the disease progresses so far before discovery is that there are no early bad symptoms. Even later, when loss of flesh occurs with irregularity of the bowels, flatulence, etc., the disease is not often suspected. It is only when symptoms of autointoxication, with sanious or mucous discharges from the bowel, occur, that an examination of the rectum is made and reveals the true condition of affairs. Operable cases are: (1) Those in which there is a chance of removing the whole mass with permanent cure; (2) those in which, though the mass is removable, the probability of recurrence is strong. In still another class, in which there is no hope of removal, inguinal colotomy should be done. The routes chosen for operation are: (1) From the abdomen; (2) through the sacral region; and (3) in females through the vagina. The second is the one most generally applicable. The line of the third sacral foramina is the upper limit of the incision. The rectum is exposed by one of the osteoplastic methods. The author generally adopted the Heinecke incision. He believed that a preliminary colotomy was necessary. This enables the operator to estimate the amount of glandular involvement; free evacuation and cleansing of the bowel are thus made possible, and, should a permanent artificial opening become necessary, the inguinal opening is much better than the sacral one. The essentials to successful resection are a clean field of operation, free descent of the proximal end of the bowel without tension, and careful su-

turing. The speaker thought that there was quite an unnecessary dread of bringing down the upper segment of the bowel for fear of sloughing. The danger was rather of pulling and stretching and otherwise depressing the blood supply. If the mesorectum and mesocolon are carefully snipped at some little distance from the wall of the bowel, the rectum can easily be brought down several inches without danger of sloughing. After suturing the cut extremities of the bowel through all their coats, Dr. Bell invaginated the proximal into the distal end and applied a row of sutures through the serous and muscular coats. He thought it was unavoidable to open the peritoneum in high operations on the rectum, but this was not to be feared if the opening was afterward closed with sutures and the site of the wound was properly dressed and drained. The question as to when the colotomy wound is to be closed depends upon the completeness of the restoration of the continuity of the bowel and upon the probability of recurrence. The operation is not without considerable danger as there are always more or less shock and hemorrhage connected with its performance. Statistics, though at all times very unreliable, show that the average rate of mortality after the operation is not greater than twenty per cent., and that ten per cent. or twelve per cent. of the patients remain well and without recurrence for four years. Dr. Bell concluded his paper by narrating briefly the history of three cases of cancer of the rectum, on which he had operated since June, 1896.

Dr. C. B. Ball, of Dublin, said that he did not perform an osteoplastic operation, but removed the lower segment of the sacrum entirely. In the osteoplastic and his operation the statistics showed that the mortality had been higher, but that may have been due to the greater extension of the disease in the cases they had undertaken to operate on. He believed the perineal route should be discarded, except, of course, in those cases in which the anus was involved. The best recoveries in these cases were those in which the tumors were freely movable. As preliminary to the operation he usually gave purgatives for several days, together with rectal enemata, to insure thorough cleansing of the bowel. Then he used a two-per-cent. solution of creolin to wash out the bowel, and then gave opium to prevent peristalsis. One danger that had been pointed out was that of sloughing of the parts. This could be avoided largely by care in manipulation. The parts should not be too tense and should not be pressed upon. He reported seventeen cases, with sixteen recoveries, from the preliminary operation. He thought that we should operate even when the cancer was high up and the glands were involved, for present relief. He preferred this operation to colotomy. In two of his cases, of ten and eleven years' standing respectively, there had been no recurrence. He thought the prognosis depended largely on an early diagnosis, for in the early stages of the disease the operation was very satisfactory. He would advise against operation if the tumor was immovable.

Dr. W. W. Keen, of Philadelphia, said that all parts of the digestive tract were now in reach of surgical treatment, except a part of the œsophagus. It was only of late years that operation for high cancer of the rectum had been attempted. There was no doubt that Kraske's operation was of great importance and offered relief to many sufferers. Even when the glands were considerably involved he had found that patients improved very much. He did not think the osteoplastic method was at all necessary. It was his custom to remove the coccyx and the adjoining portion of the sacrum, but he differed from Dr. Ball and agreed with Dr. Bell as to the advisability of doing a preliminary inguinal colotomy, whether temporary or permanent. But the two operations should never be done at one sitting. The main object of this preliminary procedure was to prevent infection of the bowel. It was better to wait two or three weeks for the subsequent operation. Kraske's view was that a preliminary colotomy was to be done only in case the obstruction was so complete that this cleansing could not be effected without it. Dr. Keen thought the operation was necessary to unload and cleanse the bowel. In many cases the two cut ends of bowel cannot be accurately joined, or the whole lower bowel may have to be removed. Colotomy is of great assistance. In one of his cases the preliminary colotomy was so satisfactory that the patient refused the radical one for removal of the cancer. The recurrence limit is four years. He reported twenty-five cases. Of these, fifteen involved sacral operations, and there were twelve recoveries. Four of these had already passed the four-year limit. He believed in prolonged purgation. He had one case in which purgatives were administered for seventeen days, and still at operation the bowel was loaded. It was a good plan to examine the urine for indican, to show if the bowel was empty.

Dr. Ashhurst, of Philadelphia, said he was never very enthusiastic about operation for the removal of cancer of the rectum, although his views had become somewhat modified since visiting Montreal, having seen some cases in which it had proved beneficial. He thought if the disease had gone on to obstruction, it was better to make an artificial anus. He was rather in favor of doing the preliminary colotomy as a safeguard, for in some cases, if resection was done without his preliminary step, there occurred a low form of peritonitis, accompanied by vomiting, so that it was difficult to nourish the patient; whereas if there was an opening in the colon, this could be used for the introduction of food, saline injections, etc., without interfering with the rectum itself. He agreed with Dr. Ball that it was better to remove the coccyx entirely. He wished to speak of one procedure of a palliative character which he found very useful; that was a small, longitudinal section of the rectum through the mass of disease in the median line posteriorly.

(To be Continued.)

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

OUR OVERCROWDED PROFESSION—PROSPECTS OF THE PRINCE'S HOSPITAL FUND—THE OTHER FUNDS—NEW NURSING-HOME—IRISH MEDICAL LOYALTY—RENOVATION OF LONDON HOSPITALS.

London, September , 1897.

Some of the newspapers have been opening their columns, during this "silly season," to the grievances of our "overcrowded profession." The correspondence has been about as instructive and will have about as much effect as previous discussions at this season. It furnishes fair copy to fill the columns of the paper, and will at once be forgotten. If the newspapers would restrict the correspondence to the grievances of the army surgeons and would carefully examine them and editorially insist on the public services being conducted solely with a view to their efficiency, we should soon have a reform. But the ventilation of the heterogeneous difficulties of private practitioners does not seem calculated to enlist the sympathy of the public. The newspapers which pretend so far to feel for our "overcrowded profession" are not ashamed to fill their columns with the doings of quacks and to receive enor-

mous revenues from advertisements they know to be lying snares for the credulous sick.

The precise position that will be filled by the Prince of Wales' hospital fund has been the subject of no little speculation in medical-society circles. What it will do and what it cannot do are points that have been freely discussed—so freely that I may as well draw attention to some of the facts, if I do not venture to add to the numerous predictions being circulated. First of all, £150,000 has been raised as donations. How much of this may be regarded as likely to be repeated yearly? Some experienced managers estimate that one-fourth of the donors will probably continue their gifts each year, so that a sum of £37,000 may be expected from this source. Add to this that annual subscriptions have been promised amounting to £25,000. Thus, apart from a considerable reserve fund that has been raised, an annual income may be expected of more than £62,000—a better result than the Sunday fund. As the Prince's fund will not close until the end of the year, it is by no means certain that the £100,000 a year originally contemplated may not be obtained—a great triumph for the Prince. The sale of hospital stamps—a suggestion of the *Daily Mail*—has been enormous, and it is thought may reach a sum of £50,000; there is talk of "hospital stamps" being made a source of permanent income—an additional triumph for the *Daily Mail*.

What will be the result of the success of the new fund on hospital finance? The more sanguine spirits allege that it will be a simple addition to hospital income. I doubt this. My experience tells me that many have given to the Prince's fund what would in some form have reached some hospitals. It is true that the Sunday and Saturday funds have not been so much behindhand this year as many feared, but it is by no means certain that they will maintain their present position. Certainly the Sunday fund will not, unless it mends its manners—a point I have previously insisted on. I have advised every one my influence reaches to give to the Prince's instead of the Sunday fund, and I know others who are pursuing the same course. This must eventually tell, and if only the Prince's advisers avoid the rocks on which the Sunday-fund committee has injured its craft it will become the most popular of such agencies. Its expenses are expected to be only about two and one-half per cent., perhaps less, and thus the money contributed to it will go direct to the hospitals without a great deduction for salaries and so on.

It is feared in some quarters that the Sunday fund or the Charity Organization Society may get a finger in the distribution of the Prince's fund. It is to be hoped that neither may, for neither is to be trusted. Burdett's "Hospitals and Charities" urges that care will have to be taken to weigh the circumstances of each institution. In reviewing that book, the *British Medical Journal* wants to know who is to weigh? The idea, says your contemporary, of a central board as proposed by the Charity Organization Society, "has been very unfavorably received by the great hospitals and very hostilely criticised by Sir Henry Burdett himself;" and further adds that "no one [unless it be Sir Henry himself] will be satisfied to put the weighing machine into the hands of the Hospital Sunday Fund." As I long ago pointed out the shortcomings of that fund, I am glad to see how naturally your contemporary is led by the same facts to this view. Another co temporary, *The Hospital*, has attempted a defence of the distribution committee, but instead of calmly examining the case indulges in ill-timed and ill-tempered abuse of the critics of the fund and charges them with not taking the trouble to ascertain the facts. It is only a weak case that the plan of abusing opponents' attorney has been said to help. The truth is that those who complain of the partiality of the distribution committee are men who have an intimate acquaintance with the facts and personal experience of hospital management.

Two of our London hospitals have closed their out-patient departments for renovation and repair, and St. Mary's remains entirely closed until the end of this month. It is not much trouble to close out-patient departments, and never seems to produce inconvenience—a fact which might be used with some effect by the Hospital Reform Association. Of course, closing the wards requires special arrangements for transfer of those patients who are unfit for discharge, and is a serious trouble to the managers, though it gives a complete holiday to all the staff. The students of St. Mary's have been granted permission to attend the practice of the Middlesex Hospital until the reopening of their own wards.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending September 11, 1897:

	Cases.	Deaths.
Tuberculosis	152	111
Typhoid fever	19	7
Scarlet fever	77	7
Cerebro-spinal meningitis	0	8
Measles	49	3
Diphtheria	131	11
Laryngeal diphtheria (croup)	6	0
Chicken-pox	1	0

The Effect of Weather on Hæmoptysis.—Dr. Egger (*Correspondenzblatt für Schweizer Aerzte*, 1896, No. 18) bases his conclusions on information obtained from the records of the Basle Polyclinic, with the following results: the change from good to bad weather, from warm to cold or cold to warm seasons, corresponds with a change for the worse in the condition of many patients with pulmonary disease. In a large number of cases coughing is increased, and in some the cough causes an increase of pressure in the pulmonary circulation and thus favors hemorrhage. Changes in the weather which favor catching cold have serious consequences; so have epidemics of bronchitis, influenza, etc.

Health Reports.—The following statistics concerning yellow fever, cholera, small-pox, and plague have been received in the office of the United States Marine Hospital service during the week ended September 11, 1897:

[illegible]

		Cases.	Deaths.
[illegible]	September 1st to [illegible]	[illegible]	[illegible]

SMALL-POX—FOREIGN.

Bombay, India	August 3d to 10th	[illegible]	[illegible]
Para, Brazil	August 14th to 21st	[illegible]	[illegible]

YELLOW FEVER—UNITED STATES.

New Orleans, La., September 10th. Up to this date there have been 1 death and 12 cases reported as suspicious to the Board of Health.

Ocean Springs, Miss., September 10th. There have been 3 deaths and 2 cases of yellow fever.

Perkinston, Miss., September 11th. One case reported, contracted at Ocean Springs.

Pascagoula, Miss., September 11th. One case reported [illegible]

YELLOW FEVER—FOREIGN.

		Cases.	Deaths.
Para, Brazil	August 14th to 28th	[illegible]	[illegible]

CHOLERA.

Bombay, India	August 3d to 10th	[illegible]	[illegible]
Calcutta, India	July 24th to 31st	[illegible]	[illegible]
Osaka and Hiogo, Japan	August 1st to 14th	[illegible]	[illegible]

REMARKS UPON THE NON-OPERATIVE TREATMENT OF CHRONIC SUPPURATIVE DISEASE OF THE ANTRUM AND VAULT OF THE TYMPANUM.[1]

BY ALBERT H. BUCK, M.D.,

NEW YORK,

CLINICAL PROFESSOR OF THE DISEASES OF THE EAR IN THE NEW YORK POLYCLINIC AND SURGEON IN MEDICAL CHARGE OF THE DEPARTMENT FOR DISEASES OF THE EAR IN THE NEW YORK CITY [illegible] ASYLUM, ETC., ETC.; FORMERLY OF THE NEW [illegible] INFIRMARY AND THE FREE [illegible] OF THE EAR, ETC.

RECENT otological literature is full of treatises which deal with the subject of new operative methods for the cure of chronic suppurative processes in the vault of the tympanum and the mastoid antrum. Of these operations ossiculectomy (for those cases in which the disease is limited to a small area within the tympanum) and the so-called Stacke's operation (for those in which the antrum is also involved) are the two representative types. It is not necessary here to enter into any further details regarding these operations or to discuss their relative merits. Suffice it to say that both of them have passed the probationary stage and are now generally accepted by otologists as safe and effective surgical procedures for the cure of the pathological conditions referred to above. Conceding, therefore, as I do, the value and the safety of these operations, I am nevertheless disposed to believe that they are resorted to in many cases in which the simpler cleansing methods would be found to be quite as effective in curing the disease. I should perhaps qualify this remark by stating that it has reference mainly to cases which are seen in private practice. In the treatment of infirmary patients it is not often possible in our large cities to devote at least half an hour, twice or three times a week, to a single case; and, furthermore, our experience in New York has shown that infirmary patients cannot be depended upon to attend the institution regularly for treatment. But, unless these cleansing procedures are carried out in a minute and painstaking fashion, and at rather frequent intervals (two or three times a week), at best only a temporary amelioration of the disease will be secured. I am satisfied, therefore, that in dealing with this class of patients, the otologist is quite right in urging the operative rather than the non-operative mode of treatment. In private practice, however, the conditions are quite different. The surgeon can give to this class of cases all the time that may be required, and the patients themselves can be depended upon to be regular in their attendance. Then again many private patients object strongly to being subjected to an operation which requires the use of ether or chloroform as an anæsthetic, and which may keep them confined to the bed or to the house for several days. It is natural, therefore, that these individuals, when the situation is laid before them, should prefer to have the cleansing or non-operative method of treatment tried first. It is not in every case, however—be it clearly understood—that we can safely offer this choice to the patient. Symptoms may have already developed which point to an extension of the disease to important neighboring organs, and in that case we must recommend strongly the more radical plan of treatment by operation—either Stacke's or the regular mastoid operation. But in most, if not all, of the cases in which a simple ossiculectomy is performed, and in quite a large proportion of those operated upon by Stacke's method, no such threatening symptoms exist, and consequently we are at liberty to deal with the problem before us in a more leisurely manner. If, in such cases, the opening in the tympanic membrane through which the pus and other products of the disease escape into the external auditory canal is fairly large—say two or three millimetres in diameter—and particularly if it occupies a high position, there can be no question about the propriety of giving the cleansing method a fair trial. On the other hand, if the opening is small—perhaps not more than a millimetre in diameter—or if it occupies a low position, the simple cleansing method is more likely to fail. But even here a limited myringectomy may suffice to overcome this drawback and so place these cases on a par with the others. If, however, the pus finds an outlet through the membrana flaccida, it is better to proceed at once to an ossiculectomy (including, of course, a myringectomy). The necessity for a Stacke's operation or for a mastoid operation in this class of non-urgent cases becomes clear when both the cleansing method and a simple ossiculectomy (including the anvil as well as the hammer) have proved unsuccessful in arresting the foul-smelling discharge.

As regards the details of the cleansing method it is enough to state here that it consists essentially of only two steps, viz., the removal, chiefly by mechanical means, of all granulation tissue, cast-off epithelium, and detritus from the diseased tympanic cavity or antrum, and the destruction by chemical means of all pathogenic germs. Injections of hydrogen dioxide through variously curved glass tubes play a very important part in the procedure, not simply on account of the germicidal action of this fluid, but largely because the active effervescence, which at once takes place when it comes in contact with decomposing organic material, aids in dislodging the obstructing substances. When once the cavity has been cleared of all these and rendered aseptic, powdered iodoform or one of the more recent antiseptic powders (europhen, aristol, etc.) should be introduced in liberal quantity and allowed to remain there indefinitely. This, in brief, is the mode of treatment which I have termed the cleansing method.

In conclusion, permit me to bear further testimony to the beneficial results which are obtained from the faithful and persistent employment of this method. I believe that I do not exaggerate the truth when I say that in a decided majority of the cases treated in this manner the results have been successful: and I base this belief not simply upon my own personal experience, but also upon that of other otologists with whom I have had an opportunity to compare notes.

[1] Read before the section of laryngology at the [illegible] British Medical Association, at its meeting in Montreal, September 3, 1897.

SOME OBSERVATIONS ON THE MANAGEMENT OF EARLY PHTHISIS.

BY J. L. C. WHITCOMB, M.D.

PERSONAL observation and a clinical experience in a large number of cases, in a climate of rare efficacy in this disease, have led me to the conclusion that, given one hundred cases of incipient phthisis, ninety may be cured by proper climatic treatment, providing only such treatment be begun sufficiently early.

It is needless, perhaps, to say that on this proviso depends the whole question of the successful treatment of pulmonary tuberculosis to-day. It is no hyperbole to state that on this point hangs the fate of millions of lives. In other words, if for any cause this factor of treatment must be omitted in any given case of phthisis, the outlook for that case more than justifies the terror and gloom which this dread malady inspires in the minds of men. Not that every case of phthisis thus left without the benefit of a proper climate goes on invariably to a fatal termination. The results of many autopsies give us reason to believe that a certain percentage recover without any treatment whatever.

In such cases the transient hypotrophy which allowed a slight invasion of the tubercle bacilli is soon recovered from. The reinforced cells rally to the rescue, and the enemy is soon surrounded and imprisoned in a mass of connective tissue, beyond whose protecting walls it may not pass. But these cases must necessarily be few; for, a foothold once obtained, the morbid products of germ activity tend still further to vitiate cell vitality already impaired below the point of successful resistance, and unless some adventitious aid be forthcoming the breach must become wider and wider until the organism succumbs. The antitoxin formed by bacillary life, and which tends to limit such processes in nutrient bouillon, seems unable to perform this function in the living organism. This fact is undoubtedly due to the blood and lymph currents, which dissipate the antitoxic principle throughout the system, fertilizing still further the soil essential to germ propagation and rendering phagocytic activity less potent. But this is digressing.

This period of incipiency, lasting from a few weeks to a few months at the longest, is the time and the only time when this disease can be attacked with any degree of certainty as to the final result. It is along this line of primary invasion that the battle must be fought, and lost or won, in ninety-five per cent. of cases. It is at this point that all the resources at our command must be brought to bear if the subsequent treatment of the disease is to be anything but a blind trusting to chance—a helpless drifting on to sure destruction. When this fundamental fact in the treatment of pulmonary phthisis is grasped in all its vital significance by the medical profession at large, then and then only will the apathy born of ages of failure give way to a healthy optimism.

While these facts are recognized in a general way, it has seemed to me that this critical period in the history of phthisis—so fraught with deepest interest to the patient—is not given the attention which its importance demands. In the early period of their disease, how many are told that they have "weak lungs; that it is only a cold, or bronchitis, or anything, in fact, but the dreaded truth?

I believe that all physicians must plead guilty to this weakness, not once, but many times. Frequently the friends are *participes criminis*, and insist that all knowledge of the real condition be kept from the patient. On what code of ethics can such practice be justified? The very life of the patient often depends on his having a true conception of his disease. No hard-and-fast rule can be formulated, but in a general way all persons over twenty years of age should be told their exact condition, while those under that age should have their family or friends as fully informed. It is safe to say that many lives have been sacrificed as a direct result of this moral cowardice of the medical attendant. This mistaken charity that would assume the added responsibility of shielding a patient from a knowledge of his disease is a very prolific source of harm in phthisis. This burden rightfully belongs to the patient and his family, and no one can reasonably ask the physician to carry it. It is a wrong, not only to the patient, but to the physician's better judgment and to the State which licensed him to practise. Let the patient face his condition at once and become familiar with it in all its bearings. This knowledge must come sooner or later; and the sooner he understands the seriousness of his disease, the better for all concerned. The mental shock and depression following such knowledge will soon give way before the hope that "springs eternal in the human breast," and we shall win the hearty co-operation of our patient in all our efforts to better his condition: also his lasting gratitude and respect, and not infrequently the longer continuance of his confidence.

While I have always held these views on this matter, my convictions have been strongly confirmed during my residence in Liberty, where my practice is largely among consumptives sent here for their health. It has been a matter of much surprise to me how few of these patients know their real condition and how many of them imagine that a few weeks in the mountains is going to make them well men and women again.

Unless there be some adequate reason which makes such a course inexpedient, I invariably set the facts of his case frankly before my patient, at the same time giving him every encouragement which such facts justify, as well as the benefit of every doubt. Having done this, I feel that half the battle is won. When the patient realizes that his return to health depends, not on a few weeks' vacation in the country, but on months and perhaps years of such residence; that it is to be a long pull and a strong pull for life—then he will make calculations accordingly and set his house in order. This means very much to persons of family or of business affairs. The mind is now no longer haunted by fears it dare not express, and the mental tranquillity which succeeds is highly conducive to physical well-being.

The one point which I wish to emphasize with all the force of which I am capable—the point the importance of which overshadows and minimizes every other consideration in the treatment of this subject—is that suitable climatic environment is the absolute prerequisite of any successful treatment of phthisis so far as medical knowledge can affirm at the present time. Of no other disease can this be said. In a nutshell, our only rational treatment is: 1st, an early diagnosis; 2d, a suitable climate. Give the patient the benefit of these, and we give him nine chances to get well to one against it. True, this is not recent knowledge: it belongs to medical classics. Yet one sees it so often ignored in practice that the conclusion is forced that it is not assigned its true importance relative to the numerous medicinal remedies, whose name is legion; many of which are forced on the profession by ambitious and designing men or through the agency of an impertinently aggressive commercialism.

Creosote or some of its derivatives, antiphthisin, nuclein, aseptolin, tuberculocidin, and many others are employed, one or all, perhaps, before the all-important subject of climate is considered, except in an incidental manner or as a means of last resort. In

the spirit that would try all things and hold fast to that which is good, I have tested fairly and without prejudice all of the above-mentioned much-vaunted "cures" for phthisis, and I do not hesitate to say that, with the exception of creosote, I consider them all of no practical value. Of creosote I shall have more to say.

What is needed is oxygen—the oxygen of pure dry air. This alone is a specific in early phthisis. It will not cure every case—no specific does that; but it will cure nine in every ten, providing enough of the remedy is utilized. And this means exercise in the open air to the point of fatigue. It matters little what form of exercise is used, so long as the lungs are expanded and the appetite is increased and rapid tissue metabolism is promoted. It is a great law of organic life that all strength comes from work; that is, the exercise of function, whatever that function may be. The muscle becomes strong from exercise; in other words, rapid metabolism. Likewise, every individual cell in the body must work or functionate up to a certain point, in order to maintain its physiological integrity. Otherwise fatty degeneration supervenes. Fat is the only tissue in the body that does not diminish and deteriorate for want of work; for it is itself potential energy. The theory has already been advanced that phthisis is but a process of fatty degeneration and that the so-called germs are but crystals of fat. While this position cannot be sustained, it is worthy of note that phthisis usually occurs in those who live and work largely indoors, who exercise their lungs the least and consequently have narrow chests. Also the usual seat of primary phthisis is at the apices, where functional activity is least. If a muscle is not used for a greater or less period of time, fatty degeneration results. Would it not be rational to infer that the same general law applied with equal force to lung tissue?

A degeneration here, however, would be modified by the presence of air, catarrhal inflammation, and tubercle bacilli always present, but which now find a favorable medium for their activity. Whether the primary condition be one of degeneration or not, all concede that there must be marked hypotrophy before the germs can step in to produce by their propagation and life processes the morbid entity known as phthisis pulmonalis. In other words, no hypotrophy no phthisis, germs or no germs.

Even if we admit that the bacilli are essential to the fully developed disease, although of secondary importance to the pre-existing hypotrophy, is this fact sufficient to constitute it a germ disease? If so, then it differs radically from all other germ diseases. It makes a vast difference in the treatment of this disease, according as we consider the germs or the hypotrophy as the main factor in its causation, and therefore the one to be attacked.

Perhaps one of the strongest arguments that can be advanced in favor of the degeneration theory of phthisis is found in the far superior results obtained in treating it as such. If an organ or a muscle be degenerated, we restore its function by exercising it and thereby promoting its nutrition. We use electricity or massage, or by the voluntary use of a striated muscle. Applying this same principle of treatment to a degenerated lung gives results that far exceed those that follow treating it with germicides. At present the germ theory of phthisis is in the ascendancy, and it seems rather heretical and reactionary even to suggest anything to the contrary. However, I am inclined to think that "not proven" would be the verdict of by far the greater number of those who see the most of this disease.

Regarding creosote, I believe that in this drug we possess a remedy of undoubted value in all forms of tuberculosis and of special value in phthisis. Given to the point of tolerance, it seems capable of exerting marked curative properties, in some cases amounting almost to a specific action. There are but few persons who cannot take it in moderate doses, while many can take large quantities of it. My experience with creosote coincides with that of Sommerbrodt, Gutmann and Beaumetz, and others as regards the greater value of large doses. I also find, in common with Burlureaux, that it has a prognostic value. Those who can tolerate large doses are much more likely to recover than those who cannot, although the former may show the greater lung involvement—although I have seen one notable exception to this rule. A lady of about thirty years of age came under my treatment three years ago. She had a large-sized cavity in the right upper lobe, and at one time was very low. She rallied, however, and became a great walker, doing her twelve and fifteen miles nearly every day. She walked herself into excellent health and returned to the city about a year ago, where she works at her profession of typewriting. This lady could not take one drop of creosote without bringing on a severe diarrhœa. She tried it several times, always with the same result.

The following case exemplifies the more common experience:

Mr. K——, aged thirty, American, letter carrier; height, five feet ten inches; weight, one hundred and sixty pounds. Came under treatment one year ago with phthisis, second stage. He was taking one of the numerous preparations of cod liver oil with two or three minims of creosote to the dose. He had been gradually losing ground, although he had been up here in the country for two months. I at once put him on creosote in capsules, increasing the dose one drop each dose until he was taking three hundred drops a day without the slightest ill effect. His urine remained normal throughout, and his stomach and bowels were not the least irritated. His appetite improved immediately and he gained five pounds the first month of treatment. He was anxious still to increase the creosote, but I advised against it. Soon after this he had to return to his duties and I lost sight of him.

The writer has taken two hundred drops of creosote a day for a week at a time on several different occasions, without causing any gastric or bowel disturbance, but with the result of producing a large flow of colorless urine of low specific gravity but never containing any albumin or casts. He has taken one hundred drops a day for months at a time without anything but the happiest results in improved appetite and increased weight, and diminished cough and night sweats and fever and other symptoms resulting from tuberculous involvement of both lungs.

I consider it one of the safest medicinal remedies we can employ in phthisis. In rather a busy practice, in which I have used this drug quite extensively for a number of years, I have yet to see the first case in which the slightest damage has been done or anything but the most trivial disturbance to stomach, bowels, or kidneys has been caused. Of course, care is requisite and these organs must be watched. I have never seen a case of hæmoptysis caused by it. I did have one experience with creosote, however, which to me was unique.

Mrs. L——, aged twenty-eight, married, had a well-marked cavity in the left lung and some infiltration of the right apex. She had spent two years in a sanatorium in the northern part of this State, where she had improved for a time. Later, however, her disease became more active and she was advised to try Liberty. She had attempted to take creosote in small doses during the early period of her illness, but believing that

it disturbed her stomach had discontinued it after a short trial. She came here about eighteen months ago, but did not improve. After being here about three months, she consulted me and I advised her to give creosote another trial. It was with some difficulty that I finally induced her to begin it in small doses and gradually increase it up to fifty-four drops a day. This seemed to be the point of tolerance with her. Her appetite improved at once and she gained eighteen pounds during the next three months.

The peculiarity of this case which made it unique in my experience was this: Instead of the cough diminishing, as is usual, it grew continually worse until I finally stopped the creosote because of this distressing symptom. The expectoration also became more abundant and changed in character. It became more of a frothy mucus, such as results from a congestion of the lungs from overexertion or from inhaling some irritating matter. It was never blood stained, however. Auscultation showed harsh breathing and moist râles over an increased area surrounding the involved portions of lung. This indicated, to my mind, a congestion in and around these tuberculous areas. In spite of this she gained in every respect, and after stopping the creosote she held the ground she had gained, while her cough and expectoration diminished rapidly. For nearly a year now her disease has been quiescent. A slight dry "hack" occasionally reminds her, however, of the damage already done and of the necessity for continual care.

This case is of especial interest, as it may offer a possible explanation of the *modus operandi* of creosote in phthisis. Beaumetz claims that it produces congestion of the lungs, and may even produce hæmoptysis. The elder Loomis claimed that when phthisis was cured it was by a process of fibrosis, the tuberculous focus becoming sequestered by a wall of connective tissue and thus prevented from doing further damage. Koch suggested as an explanation of the curative action of tuberculin that it caused a zone of congestion around the tuberculous foci, promoting thereby the fibrosis essential to a cure. Putting all these facts and theories together makes it conceivable that creosote acts by producing a certain degree of hyperæmia around the diseased tissue, and thus aiding the conservative process of connective-tissue formation. It is possible that it is this property of creosote of producing the requisite amount of stimulation of the diseased tissues which makes it the agent *par excellence* in phthisis. This stimulation if carried a little farther would be destructive instead of constructive, pathological instead of conservative. It would seem that the failure of tuberculin as a safe and curative agent lay in the fact that it carried this stimulation of the involved tissue beyond the point of reparative hyperæmia, and produced in some cases rapid destruction and breaking down of the tuberculous deposits, overwhelming the system with the products of tissue decomposition or producing an eruption of miliary tubercle over extended areas.

Perhaps we would not be justified in regarding creosote as a specific in phthisis. Yet there is little doubt that it has an elective action on tuberculous processes wherever they may occur. I know of no more efficient remedy than creosote in tuberculous arthritis, osteitis, adenitis, struma, lupus, or, in fact, the local or general manifestations of the tuberculous diathesis in any form. In this, also, it resembles tuberculin.

Besides its general antituberculous properties, there is reason to believe that in pulmonary tuberculosis it is pre-eminently efficacious, owing to the fact that it is largely eliminated by the bronchial mucous membrane, it being an excellent expectorant and pulmonary alterative in other than tuberculous affections of the lungs and bronchi. This action is seen in chronic bronchitis, bronchiectasis, pulmonary fibrosis, whooping-cough, and in other diseases of the lungs.

À propos to this subject, the matter of sanatoria for the special treatment of phthisis arises. There is much said and written of late about the advantages of treatment in such institutions. Sanatoria for the treatment of phthisis are of comparatively recent origin. A quarter of a century would cover their history. Both the medical profession and the laity turned to them with high hopes that at last a distinct forward movement had been made in the treatment of this disease. It is needless to attempt to conceal the fact that these hopes have been shattered by the results thus far obtained. The yearly reports of these institutions, with their small percentage of cures, have been a sad disappointment to all who are interested in the subject; especially so when it is considered that only the incipient and most favorable cases are admitted. Occasionally, with blare of trumpets, it is reported that one or more have been discharged cured. But very little is said about the scores who are quietly turned out to die. That all who are thus turned out worse than when they entered do not die is against rather than in favor of hospital treatment. There must be something inherently and radically wrong in the system.

About two years ago a party of five, one male and four females, came to Liberty. They had all been in a noted sanatorium in this State, for periods ranging from six months to two years. The effect on their disease of their residence and treatment there had varied—sometimes worse, sometimes better; but on the whole it had tended downward, until they were advised to change climates. This they did by coming to Liberty. Of the five, one died within three months. She was in a dying condition, in fact, when she came here. The other four are well to-day. Their improvement began at once and progressed with hardly a setback. If anything, their gain was more marked during the winter months. This is usual, however, in my experience. It was the unanimous opinion of this party, as it was certainly my own, that they would never have recovered had they been obliged to remain in a sanatorium. The life had become so intolerably tedious and obnoxious that their chances for improvement were greatly diminished at least. As one of them expressed it, "Death would have been a blessing." I find that this is invariably the case with those who have once been in such an institution and live to tell the story. Usually nothing could induce them to repeat the experience.

Could such hospitals be opened to the hopeless and dying cases of phthisis, they would subserve a useful and humane purpose. But for the care and treatment of early cases it is my opinion that such institutions are not only useless, but diminish the chances of such cases by a large percentage. I have reached this opinion only after careful study of the yearly reports of consumption sanatoria in this country and abroad, and after long observation of phthisis treated within and outside such places.

The causes for this failure are not far to seek. The all-pervading and ever-present depressing effects of institutionalism and hospitalism on the mind cannot help being detrimental to bodily nutrition. In no disease does the condition of the mind have such a powerful effect for good or evil as in phthisis, and in no disease is it so essential that nutrition be pushed to the highest possible point.

To eat, to sleep, to awake, and to exercise by the clock and under orders may be all right in a military camp, but it becomes extremely monotonous to a person ill and who desires relaxation and diversion rather than too much discipline. Too much doctor, nurse,

and treatment, too much looking after and surveillance tend to produce a morbid self-consciousness and sensitiveness to slight symptoms, altogether disastrous to healthy bodily function. In habit of thought and disposition the patient soon becomes like the typical "rounder" of the city hospitals. She studies her symptoms and treatment, and discusses them with disgusting familiarity in season and out.

The constant and exclusive association with the sick in the dampening social atmosphere of a hospital more than neutralizes all the obvious advantages of such treatment. All exercise is apt to be half-hearted, perfunctory, and void of interest, thereby losing half of its value. The outdoor life prescribed soon becomes nothing more than sitting wrapped in furs on a veranda.

That far better results are obtained outside the uncongenial influences of the sanatorium I have seen demonstrated many times. About eight months ago seven young fellows, whose ages ranged from eighteen to twenty-seven, secured board in a private boarding-house near by. They all came from New York and vicinity about the same time, and all were suffering from incipient phthisis. At present they are all well and robust, and remind one more of a party of jovial college boys out for a vacation than they do predestined candidates for an early grave. They have all gained much in flesh, and their physical signs have so far disappeared that it is with difficulty that any trace of their former existence can be found. One of them, the youngest, a boy of eighteen with rather a poor physique and contracted chest, still shows a very few bacilli in the scant sputum. Otherwise his symptoms have all disappeared.

They began to improve immediately on coming here, and with the exception of slight colds occasionally, their progress has been uninterrupted. All of them took creosote in moderate doses; also cod-liver oil part of the time. But what I considered to be the main factor in their rapid improvement was the pleasantly active outdoor life continually followed. The walks and drives, the fishing, hunting, and skating parties, and frequent excursions into the country, all planned with some definite object in view, tended to produce that forgetfulness of self and bodily function so necessary to perfect nutrition.

No aimless and spiritless wandering up and down in glass-inclosed balconies; or curling up in furs in torpid inactivity, like a hibernating animal, on open porches, can produce such results. It may be all that can be done for advanced cases, but it is certainly bad for early phthisis.

Such results as above noted have been so common in my experience that I do not hesitate to repeat the statement made in the beginning of this paper, that ninety per cent. of incipient phthisis can be cured by climatic treatment—which means an active life, out-of-doors practically night and day, for sleeping-rooms should communicate freely with the outside. And this should be in a dry climate, at an altitude of from twelve hundred to twenty-five hundred feet. I often advise young men who cannot afford to board in the country long enough to get well to hire themselves out to farmers for their keeping, and save their lives thereby. Others I have advised to club together and camp out in tents for eight or nine months of the year. I have seen excellent results from such practice. Nearly all who suffer from early phthisis are able to work, and usually do work for a year or more before they are obliged to give up. If such persons could be given some outdoor employment in a suitable climate, they would not only be self-supporting, but would get well much sooner than if they did nothing. This is the most difficult feature of the whole problem—the inability, from lack of means, to take advantage of a more favorable climate. I can conceive of no other practical solution of the question of treatment of the masses of consumptives. If those who have millions to give to charity, instead of building palatial sanatoria with luxuriant appointments which tempt to idleness, would spend but a moiety of the amount in laying out farms and gardens and vineyards in proper climates, and let those whom they would benefit do the work on them, they would not only enjoy the blessings of giving, but would have the satisfaction of knowing that their beneficence had been a benefit instead of a detriment to the recipient. At present there is much money being expended, and much thought and ingenuity are being employed in devising sanatoria that shall be perfect from a hygienic and sanitary point of view. It would seem that of all things beneath the sky that a consumptive needs, four walls to shut out the life-giving sun and oxygen would be the least indispensable. While

"Walls do not a prison make,

they go a long way toward making the sepulchre of the victim of early phthisis. Give him the broad canopy for a roof, plenty of exercise and good food—largely albuminous—in a high, dry climate, and we may almost literally in this disease—

"Throw physic to the dogs."

The colonization scheme suggested above might appear rather utopian at first. Yet I believe it is feasible, and in my opinion it is ideal. There are large and fertile areas in New Mexico and Colorado, also in this State, where the climate is all that can be desired. Thriving communities, villages, and even cities might be built up, and the whole commonwealth be benefited; while thousands could work out their destiny under conditions favorable to life and health.

In the further management of phthisis I have seen great benefit derived from cold sponging every morning, followed by a vigorous rubbing down with a coarse towel. It has a general tonic effect, and gives a feeling of exhilaration and a sense of well-being which nothing else will produce. Pulmonary gymnastics, the use of chest weights and dumbbells, also do good service in increasing the breathing-capacity.

GASTRO-JEJUNOSTOMY IN GASTRECTASIS.[1]

By A. H. CORDIER, M.D.,

[illegible]

The surgery of the abdomen, as it stands to-day, is a beautiful demonstration of surgical ingenuity and the application of methods approaching the exact, as practised by American and foreign surgeons. The peritoneum is as "sacred" to-day as of old, but modern asepsis has robbed this dangerous-to-invade sac of most of its bars to intrusion, and it is opened to-day by the painstaking, clean surgeon with very little danger. Dirty operations bring disaster to-day the same as in former years. The invasion of the peritoneum is not the only source of danger to the patient. The character and thoroughness of the work done determines the success or failure. The peritoneum is filled with hollow organs mostly, or in part, essential to life. These naturally contain myriads of pathogenic germs, and the opening of one of these organs is fraught with much danger unless the work is most carefully and exactly performed. An improperly applied stitch may lead to the loss of a life.

Most of the operations on the alimentary canal have so far been done as immediate life-saving procedures, and the chances of recoveries are not so great as in the class of cases that I propose to deal with in this arti-

[1] Read by title before the Missouri State Medical Society at St. Louis, May 20, 1897.

cle; that is, operations having in view comfort giving first, and later prolongation or saving of life.

While gastrectasis is in a great majority of cases due to some form of pyloric stenosis, there are other cases in which there is no constriction of the pylorus. The most frequent cause of pyloric stricture is cancer, yet it must be remembered that dilatation of the stomach is a chronic slow process, and it is rare that the patient survives the disease a sufficient time to permit the stomach to become dilated. In malignant cases, as a rule, the contents of the stomach are vomited before fermentation from retained food takes place, both factors in the production of gastrectasis. In the majority of cases dilatation of the stomach is not due to the presence of a malignant disease. Nature, in her imperfect work here as in many other localities, leaves a condition not directly dangerous to life, but a menace to comfort and health primarily; secondarily, the imperfect repair, or rather the results of the healing, leave a condition acting as a bar to proper digestion and assimilation, thus leading to retention, fermentation, and gastrectasis, with all the train of symptoms of a dilated stomach. The amount and character of the contents of an aggravated case of gastrectasis are surprising. Even gallons may be evacuated in rare instances. Articles of diet ingested months before, such as prune or grape skins or orange peeling, may be found very little changed.

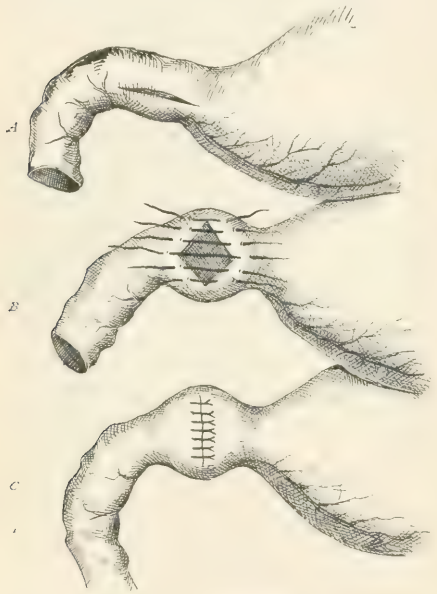

FIG. 1.—Pyloroplasty.

In dealing with the pathology of the abdomen the all-important question of diagnosis must not be lost sight of, as under the guise of the "justifiable exploratory incision" too many abdomens are opened by men who should be diagnosticians as well as mechanics. The diagnosis of the exact pathology and its source can, as a rule, be made in a case presenting symptoms of a pyloric stenosis, as practically only two conditions give rise to a stricture in this locality, one being benign (ulceration) and the other malignant. By far the majority of the cases will have a benign (ulcerative) origin, as the process of dilatation is a slow or gradual one, and will give the usual history of a gastric ulcer.

Movable right kidney, while giving rise in quite a percentage of cases to gastrectasis, does not produce that variety characterized by a persistence of the symptoms (the cause being intermittent), such as is noticed in cancerous or benign stenosis.

In a large percentage of the cases presenting themselves to the surgeon, the usual methods of irrigation, electricity, massage, dieting, etc., will have been tried with either no beneficial results or simply a retardation of the inroads of the condition on the patient's general health. Such results being obtained after months of careful handling, patients will tire of any temporizing procedure involving so much annoyance and self-sacrifice and promising so little in the way of a cure, and will gladly accept any method of dealing with their cases, having in view a permanent relief from the treatment and a fair promise of a cure of diseases from which they suffer.

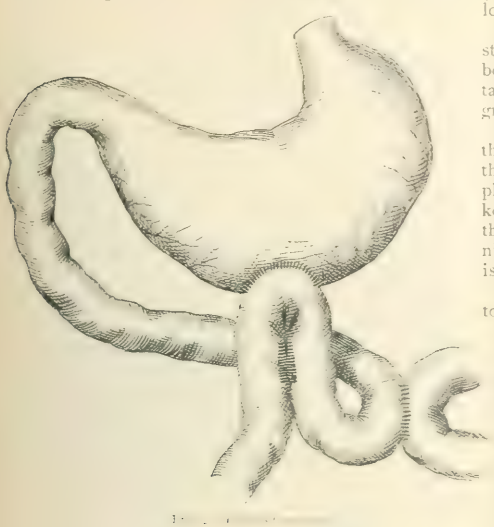
In any form of pyloric obstruction the condition is a mechanical one, and the method of giving relief must be of a like character, *i.e.*, surgical.

Loreta's operation, introduced in 1883, has not demonstrated by time and a fair trial all claimed for it by its originator. Any operation having for its aim the permanent dilatation of a cicatricial narrowing of a canal must of necessity extend over a long period of time, and that, too, with frequent divulsions or stretchings. The history of all cicatricial tissue, especially when the process of healing extended over a large muco-muscular area, is to return to its contracted state after divulsion. This is notably the case with cicatrix of the pylorus following a healed gastric ulcer. The operation of Loreta is certainly not applicable to the closure of the pylorus due to malignancy.

Pyloroplasty, or the operation devised by Heineke-Mikulicz, is one that promises very good results. It consists in making a longitudinal incision on the anterior wall of the duodenum and stomach, in all about three or three and one-half inches in length. This incision is closed in a vertical direction, or transverse to the way in which the cut was made. By thus closing the wound a new pylorus is created, with its cicatricial tissue on its posterior wall. This is a very good procedure, but is attended by unnecessary difficulties to be encountered by the surgeon and dangers to which he is unwarranted in subjecting the patient. Time is an important factor in the success of any abdominal operation, and especially is this true in the case of patients much debilitated from any cause. Many of these patients are much run down as a result of the prolonged suffering, lengthened starvation, and chronic poisoning from decomposed food, etc. Much surgical time is occupied in doing a pylorectomy or a pyloroplasty (Heineke-Mikulicz).

The muscular coat of the stomach in gastrectasis is first thinned by the dilatation, but still retains more or less of its contractile power. The organ under some circumstances is capable of making an approach to its natural size in its efforts at the expulsion of its contents through the pylorus or the œsophagus. Later the organ becomes permanently dilated, with thickened walls in an atonic state, with very little power for self-emptying. The pyloric and duodenal fixation is at a much higher point than the bottom of the sacculated stomach, hence the inability of the stomach to empty itself. Any operation having as its object the relief of this distention and retention must be made with a recognition of the above facts, and a site selected for the opening near the dependent portion of the dilated organ. This will at once be recognized as the only location for proper drainage. In reports of many cases of pylorectomy and pyloroplasty it will be noticed that the patient suffered with many of the old symptoms, and the stomach required irrigation and emptying with the tube, after-effects of the operation failing to fulfil the indications to be met by surgery.

Malignant disease of the pylorus, giving rise to an occlusion or partial closure, with a resulting dilatation, is best relieved by the operative procedure recommended in this paper. It must be remembered that when a malignant disease of the pylorus has advanced



to a period in its history when it produces a closure of the pylorus, it has also advanced beyond the limit of probable total extirpation; hence temporizing and comfort-giving surgery (by methods entailing the least immediate danger to life) is to be applied in the case. Pyloric resection of cancer, while a brilliant procedure, has not been crowned with such success, as far as cure is concerned, as would entitle it to be placed on the list of advisable and warranted surgical operations. This statement, I fully recognize, is at variance with the writing and practice of some of the world's greatest teachers and surgeons.

Dreydorff reports in a series of collected cases of pyloroplasty a mortality of twenty per cent. The same author tabulates (1894) one hundred and eighty-eight pylorectomies with a mortality of seventy-five per cent., the average duration of life in those recovering from the operation being only eleven months, Czerny's mortality from this operation being forty-one per cent. Any operation having an immediate mortality of fifty per cent. to sixty per cent., with an average duration of life of only eleven months following the procedure, should be banished from the list of legitimate surgical operations. Especially is this true when a less dangerous method is offered as a substitute.

In leaving a large cicatricial mass at the pylorus there is, as is claimed by some surgeons, a disposition to malignant degeneration at the site of the fibrous tissue, but this rare change is best averted by diverting the source of irritation (the passage of the stomach's contents) in a direction farthest removed from the scar.

Nomadic surgical procedures, or wandering surgical operations, usually result in half doing any or all methods tried. With a few surgeons the new and untried technique presents a seductive persuasion hard to resist, but the adoption of this technique is only too often disastrous to the patient. Surgical calisthenics ("keeping the hand in"), in inoperable cases of any nature, should be, and is as a rule, condemned by the majority of operators. It is useless and unsurgical to perform a pylorectomy for malignancy far advanced when it is known that nothing but a specimen and a little "surgical exercise" can be expected.

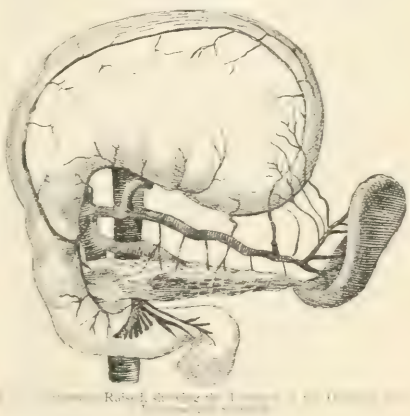
Surgical procedures of long duration on anæmic patients are fraught with much danger. Malignant disease of the pelvis soon induces profound anæmia and cachexia, both militating against successful surgical work. A pylorectomy or a pyloroplasty takes too long, as a rule, for a low mortality in anæmic patients.

Lucke, with the idea of keeping the intestinal peristalsis in line with that of the stomach, rotated the bowel and anchored it in that position. An important factor in the emptying of a dilated stomach is gravity, and not muscular action alone.

Baum's operation not only reversed the direction of the gut's calibre but made multiple anastomoses, so that the operation when completed resembled a complicated piece of plumbing, his idea being not only to keep the wave of the intestine in a direct line with that of the stomach, but to prevent the bile from running into the stomach. His operation, here illustrated, is too complicated to be useful or to be adopted.[1]

I have performed the operation of gastro-jejunostomy five times, with five recoveries. A report of one of the cases will suffice to illustrate the history, technique, and progress of the case after operation.

Stricture of Pylorus; Gastrectasis; Gastro-Jejunostomy; Recovery.—This man, seventy years of age, some eight years ago had an attack of hepatic colic, lasting several hours, followed a few days later by a jaundice persisting three or four weeks. He soon regained his former good health, and retained it until two years ago when he had another colic attack, not so severe as the first and not followed by jaundice. Two years ago he began having more or less pain and uneasiness in the epigastrium, especially noticeable after eating. After two or three months of this uneasiness he began losing flesh and had occasional spells of vomiting. No blood was vomited at any time. When I first saw him he had not been able to retain or digest much solid food for several months and was greatly emaciated. From his former weight of two hundred and forty pounds he was reduced to one hundred and thirty pounds. His appetite was fairly good, and liquid nourishment was taken with a relish. Solid food caused pain and nausea until relieved by vomiting. Upon examining him I find that he is greatly emaciated and has a "swarthy" look, not exactly a malignant cachexia. Pulse and temperature normal. Examination of the abdomen reveals a greatly dilated



stomach, its peristaltic action being plainly felt through the thinned abdominal parietes. No pain on pressure in the region of the pylorus. Here an unnatural sense of resistance can be plainly and distinctly made

City.

out, covering an area about as large as the palm of the hand, or smaller.

A diagnosis of a malignant stenosis of the pylorus was the most acceptable theory to me, yet a non-malig-

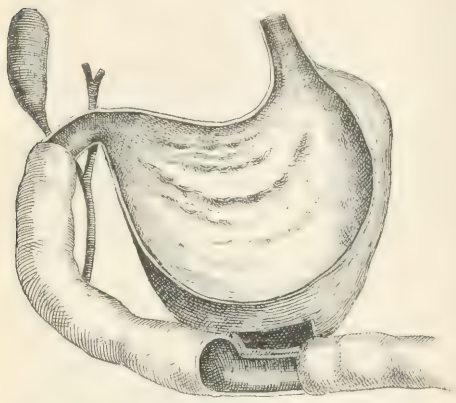


FIG. 4.—Showing the Location of the Openings after the Operation is Completed.

nant stricture had been diagnosed by a good diagnostician before I saw the patient. He was given a tonic of iron and strychnine, and nutrient enemas were ordered in the twenty-four hours. Under this *régime* he gained eight pounds in thirty days.

An operation was advised and assented to. A median incision, four inches long, extending downward from one inch below the xyphoid cartilage was made. A loop of jejunum was pulled into the incision, the transverse colon and the omentum were pushed upward, and a spot in the colon mesentery free from blood-vessels was selected and an opening made through it, thus exposing the posterior wall of the stomach. A portion of the latter being pulled through this opening, the most dependent part of the stomach should be selected for the site of the anastomosis. A puckering-string stitch was then put at the proposed site of the new opening, and a similar procedure was carried out with the jejunum. The opening in the jejunum was made first, and one-half of the largest intestinal Murphy button put in, the other half of the button being inserted in the opening now made in the stomach. The button was pushed together, closely approximating the jejunum and stomach serous coats. Care was taken that no fold of the colic mesentery was included in the grasp of the button. An additional "backing up" Lembert stitch was run around the button, and the operation completed by closing the parietal incision. The patient vomited for the first time ten hours later. The bowels moved on the second day. His convalescence was uninterrupted. He is alive to-day and has gained sixty pounds. He has had no return of any of his former symptoms of pyloric stricture or gastric dilatation. Evidently the stricture was a non-malignant one, as the operation was performed over two years ago.

The history (clinical) of these cases will vary only as the pathology is of a different character or severity. The operative technique is about the same in all cases. The cardinal point to recognize in operating is to make the opening in the stomach in a location that will drain the indolent organ.

I append the history of an aggravated case of gastrectasis following the cicatrization of an ulcer near the pylorus. The patient being an intelligent physician, I give his own description of his case:

"RAYMORE, MO., April 24th.

"*Dr. A. H. Cordier, Kansas City, Mo.*

"DEAR DOCTOR: In 1862, while in the army, I noticed first a pain at the pylorus. Continues after a few weeks from its inception. This was present in greater or lesser degree until about July, 1865, when I became much worse. Accompanied with pain were indigestion, flatulence, and a sense of distention. I was actively engaged in a large, laborious country practice, and kept up, although steadily losing weight. In October, 1865, I did an enormous amount of work, and in November was doing more. At 3 A.M. on November 9th I awoke, feeling faint and sick, and attempted to rise, when I fell off the bed, unconscious. My wife raised me up and I commenced vomiting. As I had eaten no supper, the contents of the stomach ejected showed pure blood. I bled and vomited by turns until death seemed ready to claim me then and there. I finally recovered, and for four days lay on an inclined plane to supply the brain with blood. In February, 1866, I resumed my practice, but the same old stomach trouble kept up—stomach full of gas, contents fermenting, and a general disturbance of the digestive process. On October 24, 1869, I had another hemorrhage, and in August, 1872, another, and the last. From this on I found that my stomach was constantly troubling me with the usual symptoms of acidity, etc. In 1888 I finally found that my stomach was dilated, and I would take a hypodermic injection of

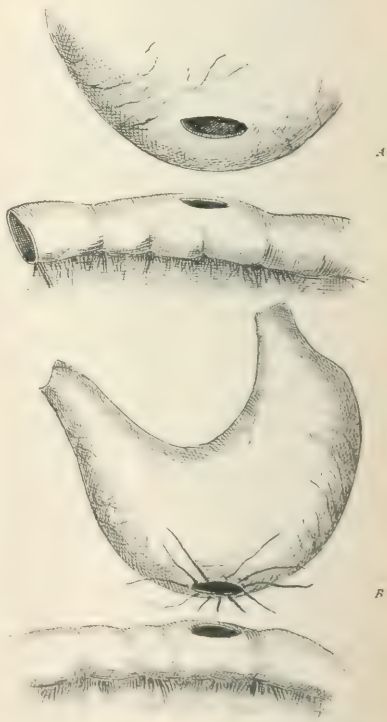

FIG. 5.—*A* Shows the Opening in the Stomach Made too High on the Wall of the Organ. *B* Shows the Correct Position of the Opening.

apomorphine to empty it, and then measure the contents. Four to six, and one time seven quarts was found. My friends used to say, 'Doctor, you are getting a big belly on you,' joking me. In 1890, seven years ago, I commenced the use of a stomach tube and

lavage. At that time the greater curvature rested on the pubes, and the epigastrium was flat or retracted, the stomach's contents, by force of gravity, pulling the stomach out of position. After washing the stomach I often used hydrozone in water, and still do when I want to have a general cleaning up of the organ. From 1890 up to date I have used the stomach tube twice every day, and sometimes three times, which amounts to at least five thousand times. The time I use the tube is before dinner and supper. I have formed the habit of lying on my right side at night, thus turning the stomach on end and the pylorus down, and by force of gravity and remaining so long in that position, the process of digestion is carried on, and the contents pass the pylorus. For the reason (I suppose) of loss of elasticity, due to dilatation, and the stenosis, the contents from morning to evening are not carried through, only in a partial way, hence the necessity of removing residuum before dinner and supper. Being a medical man, of course I looked closely after my case, and to the use of the tube lavage I owe my life to-day. At present I use three pints of warm water to wash the stomach, but I have tried to see how much the stomach would hold, and seven to eight pints will fill the stomach and drag it down to the pubes. My theory is that I had a bad ulceration at the pylorus, which finally healed, producing stenosis from cicatrization, and in turn this caused dilatation of the stomach with all its troubles. My weight fell from one hundred and fifty-five pounds to one hundred and seventeen pounds and I never have reached more than one hundred and thirty-five pounds since. If I am situated so that I am unable to wash my stomach I dare not eat, but must omit the meal until I can (except the morning meal). I often have pain now, mild in character, at the pylorus, but it is not continuous.

"I can truly say that had I been a layman I should have long ago been dead, for it is only by the unremitting care that I bestow upon myself that I am so well. Truly and fraternally,

"W. W. Johnston."

Deductions.—1. Cancer of the pylorus, even though removed, returns quickly, and always kills.

2. Pylorectomy is attended by a high mortality and is not a justifiable surgical procedure in advanced carcinoma of the pylorus.

3. Gastrectasis due to a malignant closure of the pylorus is best treated by a gastro-jejunostomy.

4. The operation as advised by Von Hacker best meets the indications.

5. It is not necessary to twist the bowel, in making the anastomosis, to prevent the bile from entering the stomach.

6. The anastomotic opening in the stomach should be at the most dependent point of the dilated organ.

7. The operation is attended by a low mortality.

8. In all cases in which marked dilatation of the stomach exists, accompanied by emaciation, pain, and invalidity, the operation of gastro-jejunostomy should be performed.

9. The relief of pain, due to the effort of the stomach to relieve itself, follows this procedure at once. The patient gains rapidly in weight and if non-malignant disease be present his former good health is restored.

Emergency Tracheotomy.—Waste no time in giving an anæsthetic. In diphtheria there is already a blunting of the sensibilities. In cyanosis and coldness of the skin the sensitiveness to pain is greatly diminished. In burns of the pharynx and larynx be ready to operate at the first evidence of sudden grave dyspnœa.

IDEAL ANÆSTHESIA.

By Rawlings Nichol, M.D.,

New .

Nowhere in the domain of surgery may graver injustice be done to the skill and reputation of the practising surgeon than in that class of cases which must be left unfinished, or, at best, in a condition far from satisfactory to the operator undertaking the surgical procedure, because of an unsuccessful narcosis.

There are in use two agents, chloroform and ether, under the influence of which most of all grave surgical manœuvres are conducted; in the remainder combinations of these, made with and without the addition of alcohol or the passing of oxygen or nitrous oxide through them, are employed. As yet we have no agent that is superior to the two playing the first rôles in the earliest history of anæsthesia; at present the real issue proposes a choice between them.

It cannot be doubted that if we measure future progress by our present improvement over measures in vogue but a few years ago, a safer and better anæsthetic will soon be at the disposal of the operator. There lurks in my mind a modest suspicion that when the realms of electricity shall have been somewhat more explored one may be derived from that source, enabling us to place our patient in a condition of unconsciousness, from which he may return to consciousness not shocked but rather exhilarated.

Chloroform.—The manner of administering chloroform or ether differs but little in the gross particulars. In the majority of cases chloroform is the best agent; in some it is the least dangerous, and in the hands of a skilled anæsthetist its risks are reduced to the minimum. A considerable series of experiments, including actual exhibitions, numbering over five hundred, with this agent, has impressed me with the accuracy of this conclusion. Different anæsthetists apparently attain equally good results with different agents; therefore, by leaving the choice of an anæsthetic to such an individual, the best results are most likely to obtain. In this connection, as the responsibility of a successful narcosis rests upon him, it is well to allow him to use such agent or agents as in his skilled judgment he considers best adapted to the case in hand. Practice develops a perspicacity which anticipates the peculiarities that mark types of individuals, and his training develops perceptive faculties which intuitively guide him to successful results. Dissimilar types require distinctly different methods; certain subjects present marked varieties of pulse, respiratory sounds, changes of color, degree of conjunctival reflexes, etc., and each has its peculiar natural significance. While the patient is being brought, or is "under" the influence of the anæsthetic, the practised anæsthetizer notices little gradations of symptoms easily escaping the observation of the occasional administrator, disregarding those which possibly alarm the tyro, while feeling grave anxiety where the casual and untrained observer thinks all is progressing favorably. Most of this knowledge is empirical, practical experience being the only possible method of obtaining it. To use but one favored anæsthetic, irrespective of the operation or type of subject, is now a thing of the past. An anæsthetic to commend itself to comparative consideration should possess these qualities: Safety; least disagreeable to administer; best calculated to produce muscular relaxation, followed by no ill effects, as vomiting, catarrh, etc.; not affecting prejudicially the question of hemorrhage; best adapted to the prevalent characteristics of the patient.

As before noted, chloroform will fulfil these requirements in the majority of cases, especially if the kid-

neys, heart, or lungs are diseased. The two conditions which to my mind might constitute occasion for hesitancy in giving an anæsthetic are the later stages of pulmonary phthisis with marked emphysema, and severe right cardiac diseases. Any interference with the patient before he is profoundly "under" should be deprecated, as in the condition of imperfect anæsthesia the dangers are considerably increased, the frightful mental phantasmagoria possible in a semiconscious state necessarily contributing greatly to the existing or induced shock. Chloroform's most brilliant field is in laparotomy, suturing of large surfaces, operations by night; in extreme old and young subjects, brain surgery, acute and chronic inflammatory and catarrhal affections of the respiratory tract, chronic endarteritis, renal disease, obstetrics, operations on chronic alcoholics, removal of tumors or foreign bodies from the larynx; in those delicate and minute surgical operations which require for their successful performance absolute quietude; finally, in all conditions in which expedition is of vital importance.

Chloroform's greatest recommendations are its rapid action, its easier administration with fewer unpleasant attendant consequences, and its less-irritating effects on the respiratory organs. Shock is less after a narcosis with it than with ether, though it must be conceded that the immediate dangers are greater with chloroform, while only the remoter ones obtain with ether. It is not possible fully to estimate the actual relations in this respect, but the dangers attending chloroform administration may be almost eliminated by the two safeguards of proper preparation of the patient and a rational administration of the anæsthetic.

Chloroform is suffering from past practice, when it was given to a degree and in a manner which would not now be tolerated. Numberless operators prefer ether to chloroform, as at some time in their experience they had a coincident death from the latter, causing them to abandon its use. The mortality from chloroform seems to be much greater than that from ether, but frequently grave disorders, such as pneumonia (especially frequent and fatal after laparotomy), bronchitis, broncho-pneumonia, œdema of the lungs, and nephritis, result from the exhibition of ether, and deaths from these complications ought to be regarded as equivalent to deaths from anæsthesia. Doubtless these effects are caused by the chilling of the blood stream or the immediate action of the intense cold on the lungs and the necessarily excessive elimination of ether by the lungs and kidneys, after it has been disintegrated by the economy. Körte and Wunderlich affirm that chloroform irritates the kidneys more than ether, and they are supported in this by Wyeth, of New York, who has made extensive reports upon this particular, but this is hardly the general opinion. I hope to submit comparative data with respect to this issue in the near future.

Preparation of the Patient.—He should have had no solid food for at least eight hours preceding the time of operation; if very feeble, concentrated and readily assimilated liquid nourishment (not milk nor beef tea) might be given up to within three hours of the contemplated commencement. Experience has induced me always radically to discountenance the so-called "ether breakfast." A mild saline purgative the evening before and a rectal injection of warm water immediately preceding the time set for the operation are a *sine qua non* to an easy and featureless anæsthesia. Even in emergency cases, when haste is demanded, a high enema or gastric irrigation, or both, ought to be insisted upon; this will minimize if not absolutely prevent the state of excitement, and will increase the efficacy of the least amount of the anæsthetic used, a feature always superlatively desired and demanded.

The stage of excitement marks the period in which most of the fatal cases of syncope have taken place, a term which has been in the past ofttimes a misnomer for obstructed respiratory function. If the patient struggles violently, we should raise his upper and lower extremities in the air, removing the fulcrumage upon which he can pivot his strength, making it comparatively easy to prevent him doing himself or attendants injury, and at this time the anæsthetic should be pushed, as struggling is the chief symptom of incomplete anæsthesia.

Frequently, with novices as anæsthetists, the struggling patient has projected upon him the assistants present, the surgeon orders more chloroform, which is hurriedly thrown into the cone and the face piece closely applied, and this is speedily followed by a stage of suspended animation, artificial respiration, anxious inquiries for brandy, strychnine, nitrite of amyl, ammonia (any of which are rarely at hand); then inversion of the patient is tried; a galvanic battery is frequently employed but is of little use; the *tout ensemble* is general demoralization of all concerned, and after a more or less extended period of this kind the patient may be resuscitated and the operator enabled to begin or complete the operation. It cannot be expected that the surgeon will be at his best after the excitement just encountered, and he is morally certain to complete his labors in the shortest time possible, fearing another excursion of his patient within the environs of death. A rarely recognized danger at this stage of anæsthesia is the rupture of some of the smaller vessels in the brain, giving us paralyses of various groups of muscles, often ascribed to the toxic effects of the agent upon the centres, but generally of mechanical origin.

The clothing of the body should be of the lightest, yet sufficiently warm to prevent the patient from being mischievously influenced by the fall of temperature incident to anæsthesia. The thoracic movements should be in plain view of the anæsthetizer, since a close observation and vigilant attention to the preservation of the respiratory function are absolutely necessary. When I speak of respiration, I do not mean fitful and feeble contractions of the diaphragm inadequate to the slightest ingress or egress of air to the lungs. The habit of females dressing for the occasion in belaced and berufflled chemises ought to be prevented by the physician's orders.

The Position.—This should, if possible, be the recumbent, or if preferable on the left side, with the head slightly extended, the means being at hand of promptly lowering the head to any degree desirable. The head should rest on a small pillow, the face be smeared with vaseline, and the patient instructed to count or talk as long as he is able.

The cone should not be closely applied to the face until the sensibility of the glottis and nasal mucous membrane is dulled.

When the patient is "under" the influence of the anæsthetic, I am in the habit of passing a curved needle, threaded with broad silk, through the tongue, as it gives one complete control over that organ, allowing it to be pulled forward instantly if necessary, and leaves but a small wound rarely noticed by the patient, giving him considerably less pain or trouble than when the tongue is held by the ordinary tongue forceps. Of the latter, I use a pair the blades of which cannot become disconnected; the ends are broadened out into a circle, of which the centre is punched out, allowing the needle to be passed through them without trouble. I find them extremely useful. If the patient gives the slightest sign of commencing to vomit or retch, the anæsthetic should be pushed to cut off the vomiting reflex.

Respiration, color of skin, condition of pupil, and

pulse claim my closest attention. Gaskell and Shore in their brilliant series of demonstrations proved that chloroform stimulates the vasomotor system until long after the respiratory centre is paralyzed, and this discovery, added to others of theirs on the condition of the heart musclè during anæsthesia, made clear how the pulse is prevented from betraying the condition of the heart during chloroform narcosis.

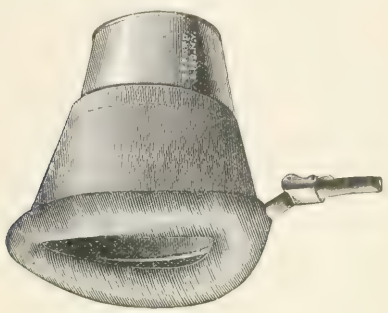
Time of the Operation.—The time of the day most suitable to administer an anæsthetic is in the morning hours; when possible, it should be so chosen, as it allows the patient refreshing sleep to fortify him for the ordeal. Thus we may take advantage of a night's rest and all the salutary effects that are associated with it, leaving the nervous system in the best possible condition and in an essentially tolerant mood successfully to cope with the great changes about to be undergone by it; at this period of the day the physical and psychical forces most nearly approach a condition of happy equipoise that is such a desideratum in anæsthesia. A factor of importance has ofttimes appeared in my experience to be the punctual observance of the time set for the operation, it doing much to prevent hysterical attacks in those who have steeled their nervous system to undergo the contemplated surgical procedure and only weaken as the time slips past the hour originally engaged.

The practice of giving either morphine, chloral, caffeine, alcohol, or similar drugs, is generally reprehensible, except, as in very rare instances, when their exhibition is indicated because of certain peculiar conditions. They seem theoretically correct and their administration is a routine practice, but careful consideration has impressed me with a desire to avoid these frequently mischievous and superfluous addenda. After the operation each has its clearly marked occasion for exhibition, but now the operator has become the sole judge of their propriety. Morphine increases the liability of asphyxia by strongly antagonizing the reflex phenomena, protracting the return to consciousness after the operation is completed, and thus frequently demoralizing the patient's friends, mayhap the surgeon too. Added to these undesirable sequelæ may be an unexpected opium or other narcosis supplanting the anæsthesia. Vomiting, at this stage especially dangerous, is frequently caused and invariably intensified by the practice, and a dangerous train of symptoms may be incited by even a relatively small hypodermic injection. It obscures signs of the greatest importance to the administrator, prolongs unduly the stage of excitement, naturally followed by a corresponding degree of wasted natural force. The temperature sinks considerably lower than in ordinary anæsthesia, and headache and nausea are its most constant results. The only point which can in any way recommend it to the surgeon is that it lessens the amount of the agent necessary to produce anæsthesia, but, as pointed out previously, the successful anæsthetist can accomplish this without its aid. Koenig abandoned this practice after a deliberate trial to test its efficacy and desirability in thousands of hospital and army cases, concluding it to be either positively harmful or at best of no benefit. Recently a new method of administering chloroform has been proposed by Dr. M. Rosenberg, who contends that the greatest dangers to both heart and respiration are occasioned reflexly by the irritating action of the chloroform on the termination of the trigeminus distributed to the mucous membrane of the nose, and that this may be obviated by first anæsthetizing this membrane with cocaine. Having tried this method in fifty cases, he concludes that the commencement of anæsthesia is less disagreeable to the patient, the excitement stage is often wanting and always slight except in alcoholic cases, and that it is rare that a patient vomits; if he does there is but little retching, and when he awakes he has no disagreeable sensation and is not haunted by the smell of chloroform or ether. His method is to direct the patient to blow his nose, thus clearing the mucous membrane; then leaning forward or sitting (never lying), to snuff a centigram of a powder consisting of ten-per-cent. cocaine muriate and some inert substance, repeating this in about three minutes before general anæsthesia is commenced. Another method to obtain the same result is proposed by Dr. A. Guerin, of Paris, who advises that the nose of the patient should be held by the fingers until general anæsthesia is produced, when there can be no longer any reflex action through the terminations of the nerves supplying the nasal mucous membrane, if the chloroform is inhaled exclusively through the mouth. Dr. Guerin rightly claims that when death occurs from stoppage of the heart, the cardiac muscle ceases to contract under the influence of the reflex action exerted by these nerves on the pneumogastric, stimulating the inhibitory power of the latter on the heart; he further shows that when a rabbit is subjected to tracheotomy, and then made to inhale chloroform directly through the trachea, the drug has no effect whatever on the heart; on the contrary, when it was held before the nose of the rabbit, the heart almost immediately stopped. The trachea being cut transversely, it is obvious that the chloroform inhaled by the nostrils could not reach the heart through the bronchi; therefore the doctor assumes that the anæsthetic agent exerts an injurious action upon the movements of the heart through the intervention of the nasal nerves and cardiac branches of the pneumogastric, the former acting reflexly on the latter. I have tried both these practices and they have given excellent results in a few of my late cases.

The essential characteristics of an anæsthetizer are the possession of a knowledge of the subject as far as it may be gained by constant and practical study, and familiarity with the literature, especially that concerned with the portrayal of clinical cases and accepted statistical records growing out of the use of anæsthetic agents. He should be gentle, quick, perfectly cool and self-contained, courageous, not rashly bold or liable to lose his nerve or head at critical moments. He should possess in the greatest degree the *suaviter in modo et fortiter in re*, as there is no contingency of a professional character that requires such tact and velvet-tongued diplomacy as when he has to soothe a semi-sensible or hysterical patient in order to continue or commence the administration of an anæsthetic. The trained operator of this description, with his thoroughly equipped satchel and his special experience, both to stand in good stead at critical moments, cannot fail to aid the operator to obtain best results and be necessarily of use in every well-planned *séance*. The demand for specialism in this branch of medicine is obvious and will tend to effect a notable saving of human life. With regard to the equipment, I make it a point to carry my own supply of chloroform and ether obtained from reputable manufacturers, stored in small containers sealed and protected from the action of light, enabling one to dispense with anæsthetics which have been kept for an indefinite time on drug-store shelves, exposed to conditions extremely liable to promote their decomposition; I never use any anæsthetic left over from a previous case, for after it has been uncorked it rapidly deteriorates.

Essentials for Administration of Anæsthetics.—An open and closed inhaler (I prefer Townshend's and the small modified Clover inhaler), chloroform and ether, Ferguson mouth gag, tongue forceps, needle holder and needles, a pocket or tracheotomy case, hypodermic syringe, and tablets of strychnine, nitroglycerin, atropine, morphine, digitalin. Aqua ammoniæ fortior and a silver catheter are sometimes of use.

The many complicated and cumbersome apparatuses to be found at all surgical-instrument makers', intended to dilute and automatically administer the vapor, are the illogical result of the fallacious premises that the anæsthetic agent must be accompanied by definite proportions of atmospheric air. Any complicated mechanism in the construction of which intricate valves are employed (to get out of order at unfortunate moments) are to be decried. The simpler the device for giving the vapor, the more serviceable and satisfactory will it prove. Of late I have employed



one devised by Dr. Townshend, of this city, with excellent results for either agent; it is modestly simple, cannot get out of order, and it is possible thoroughly to cleanse it instantaneously. The older ones frighten patients immediately they see them, especially children and hysterical subjects—certainly not to be wondered at considering the lethal-like aspect of the majority of these pseudo-scientific toys.

From the teaching laid down by men clearly untrained carefully to observe or practically unacquainted with the phenomena of anæsthesia, fallacious ideas have been associated with various inhalers, so that operators proceed with the idea that no harm can occur to the patient if the vapor is measured with one of these automatic contrivances. The susceptibility of patients to anæsthetics is not governed by any law that applies with equal force to all individuals; therefore, to prescribe definite hard-and-fast rules to all is, to say the least, poor practice; on the contrary, they may be adapted with special significance to the peculiarities of each subject. Idiosyncrasies, disparity of temperament, the latent strength of the patient coupled with his occult moral force, physical conditions, the position and preparation of the patient, and numerous other concomitant features are all factors of little importance to the occasional administrator, but pregnant with meaning to the specialist. These factors cannot be regulated by any known mechanism, however subtle; the rôle each plays has to be approximately gauged by the skilled anæsthetist, constituting in a great measure the necessity for his aid. Numberless patients have been asphyxiated and the result has been calmly chronicled as being due to a greater percentage of vapor than the human organism can safely tolerate.

Chloroform Syncope.—This term is universally accepted as the correct designation of the sudden deaths occurring in chloroform narcosis; it may happen when only a few whiffs have been inhaled, but there is no doubt that primary syncope is returned as the cause of death when it could be traced to other causes. Dr. Richardson says: "I should be inclined to put down 'fear' as one of the most determined causes of fatality from chloroform anæsthesia. I have before me now several instances in which it is impossible that chloroform—minus fear—could have been the direct cause of death, because sufficient of it was not administered to produce this result." To avoid this danger, it is absolutely necessary that the patient should be completely anæsthetized without anything to disturb his quietude, being cheered and comforted by the anæsthetizer alone; all hysterical relatives and friends should be kept from him; if he has a dear friend, who is of sterner stuff and for whom the patient has great affection, he may be allowed to stand near him or hold his hand. All talking, slamming of doors, or the rattle of instruments about to be used should be prevented, and it is imperatively desirable that not even the locality to be operated upon be uncovered or examined until he is completely narcotized. Necessarily, patients with fatty hearts, aortic or advanced mitral lesions, are more liable to syncope. A point of some importance is the fact that robust and vigorous patients form the greater proportion of those who have these attacks at the initial stage, frequently, no doubt, due to the fact that the chloroform is timidly given, instead of the anæsthetizer rapidly pushing on to complete anæsthesia. Syncope occurring in the second stage of anæsthesia is probably due to the reflex inhibition of the heart through the vagus; its most dangerous stage is just before the patient sinks into complete surgical anæsthesia, and it seems that at this period a special sensitiveness of reflex mechanism is brought about, death occurring from apparently trifling causes, frequently in attempts at vomiting.

In case of intestinal obstruction and like conditions, this particular time seems to be fraught with peculiar danger; at this stage the anæsthesia must be pushed rapidly to completion and the patient kept thoroughly "under" until the operation is finished. If the syncope is profound the chloroform must be removed, investigation made to discover if any coincident asphyxia is present, and the cause eliminated. Artificial respiration, with or without the use of Fell's apparatus, is to be employed; flagellation with towels alternately wet with hot and cold water; pressure on the floating ribs; rhythmical traction of the tongue; fresh air admitted into the room in plenty; hot saline solution thrown into the rectum; nitrite of amyl and ammonia by inhalation; strychnine, nitroglycerin, and ammonia hypodermically. Stretching of the sphincter ani is often an extremely good measure. I have but little faith in oxygen or the use of a faradic battery; the latter stimulates the vagus and increases the inhibitory action of this nerve, seeming to me positively harmful; by pressure on the lower ribs and carefully conducted artificial respiration the phrenic can be stimulated to excite the diaphragm. Traction on the tongue can be employed to prevent the approximation of the aryteno-epiglottidean folds, thus allowing free ingress of air to the lungs and removing the chance of accident from the tongue falling backward upon the epiglottis. It was pointed out some time ago by a careful observer that rhythmical traction on the tongue will stimulate respiratory movement.

Syncope occurring during the third stage of anæsthesia is least frequent and is due to an overdose acting on the intrinsic centres of the heart in this muscle itself (Ludwig, of Leipsic, and Von Recklinghausen showed that the heart is under the control of these ganglia and can perform its normal mechanism even when disconnected from the brain or cord) or to paralyzation of the nerve centres in the medulla. Doubtless a great portion of the mischief comes from the carbonization of the blood in the capillaries of the lungs, retarding the stream until this reaction is felt by the larger vessels and culminating in paralysis of the heart muscle in the effort to empty its ventricles. The concentration of the anæsthetic atmosphere is not of so great importance at this stage of the narcosis as is the amount of chloroform circulating in the blood.

"The amount coming from the inhaler varies greatly from time to time as fresh anæsthetic may be dropped into the cone; the danger exists greatest when the most concentrated vapor coincides with the period when the patient is inspiring deeply" (Lister). The treatment of syncope occurring during complete surgical narcosis is practically the same as outlined for that occurring during the second stage of anæsthesia, with the marked exception that the anæsthetic must be removed and fresh air in abundance admitted into the room.

The administration of a few doses of digitalis or strychnine hypodermically in subjects with weak hearts was recommended and practised by the late Dr. Wood, who was a firm believer that it lessened the danger of syncope and that it could be profitably employed in most cases.

If it is ever necessary to perform tracheotomy on a patient, the method proposed by Dr. Von Donhoff, of this city, being so simple and requiring such an infinitesimal time renders it of momentous service in connection with spasm of the glottis, occasionally happening in narcosis. A curved needle threaded is passed through the trachea; then the tracheal rings are cut, and the thread is caught by a blunt hook; this thread is divided in the middle and the two strings it forms are loosely tied at the back of the neck.

Ether.—"Any one can give ether" has been the stereotyped cry of surgeons of the last decade, when the question of a suitable anæsthetic in a given case has had to be considered. Of late, this belief has been renounced by many of the most able; certainly those who have had considerable practical experience in the administration of this anæsthetic are the firmest believers in the renunciation, readily affirming that it requires a greater skill to administer ether than chloroform. It is not so apt to kill the subject on the operating-table, though grave dangers are encountered hours or days after the surgical *séance;* these are often lost sight of or ascribed to other causes.

Eliminating asphyxia, but little is known by even our advanced physiologists of the manner in which anæsthetics kill; no one has discovered the subtle secret, though plausible theories have been advanced by the score. In records of autopsies of death from anæsthetics, how often is the return marked: "All the organs were healthy and the cause of death was not shown."

The preparation of the patient should be the same as prescribed for chloroform, especial care being taken to secure an empty stomach and to insure that the patient is kept warmly covered, hot water bags being applied to the extremities if necessary, as the fall of temperature is greater when ether is used. The first few inspirations should contain only a small quantity of ether vapor until the sensibility of the glottis is dulled, the administrator gradually increasing the amount until the stage of excitement is reached, then pushing the anæsthetic until surgical anæsthesia is induced and keeping the patient thoroughly "under," accomplished by a small amount of ether if judiciously administered. The anæsthetizer should be prepared to meet at the onset any difficulties of respiration that may arise, the delicate circulation in the lobes of the ears giving ample warning of disturbed circulation; if present it is to be promptly met by allowing the patient to breathe one or two inspirations of unmodified air. The patient should not be removed to a cooler atmosphere until he has recovered from the anæsthetic; indeed, it is well to keep him for about twelve hours in a warm room to minimize any bronchial trouble that may occur as a result of the etherization. This is especially important if infants or elderly people are the subjects. If a closed inhaler is used, the patient should be allowed a breath of unsaturated air from time to time, best accomplished by removing the cone from the face. If ether is incautiously pushed for a prolonged period without allowing the patient to renew the air in his lungs from time to time, his respiration may stop, although the muscles may be flaccid; this condition appears to ensue from the overloading of the blood with ether, leading to paralysis of the respiratory centre and a condition of collapse similar to the syncope of chloroform narcosis. The increased secretion from the mouth and respiratory tract should be occasionally sponged out, but the experienced anæsthetizer encounters considerable less of this disagreeable symptom than the novice. Vomiting and coughing should at all times be overcome by pushing the ether to tolerance. Warning of vomiting is generally given by the occurrence of irregular, shallow breathing, yawning inspirations, efforts at swallowing, retching, and dilatation of the pupil. The latter sign must be differentiated from that which occurs when syncope is about to be induced; it is one of the most dangerous symptoms, and its true import should be instantly recognized. In case of the administration of ether to patients in a state of collapse, very dilute vapor must be given, the room kept about 85° F., and dry heat applied to various portions of the subject. Schilling is in the habit of giving one-grain doses of camphor hypodermically as a stimulant, reporting good results from this procedure.

The following conditions are looked upon as being specially suited to the administration of ether, but mitigating circumstances, as with the field mapped out for chloroform, may contraindicate its use: surgical shock, epilepsy, tendency to syncope, fatty heart or advanced aortic or mitral disease, acute alcoholism and delirium tremens, fatty or obstructed liver, spina bifida, hydrocephalus, when any heart-depressing drug has been administered in large doses. No alcoholic stimulant should be given before or during collapse following or occurring at its administration; it only increases the narcotization, and therefore the dangers; for the same reason opium should also be withheld.

Obstructed respiration may occur from simple falling back of the tongue, the presence of blood, mucus, etc., in the the larynx, or from spasm of the glottis. A good anæsthetist can administer this agent to patients of any age, but it will be generally found that elderly people do best under chloroform, they having often a condition of chronic bronchitis.

In aortic diseases it acts as a stimulant and is often beneficial, but if there is a tendency of the venous system to be turgescent, as in mitral diseases or dilated right heart, chloroform will be more suitable, if administered on right principles.

Ether exercises a much less dangerous action on the ganglia of the heart; this would relegate chloroform into disuse but for the fact that the after-effects of its administration are often so dangerous. Thus the superior safety of ether is frequently more than counterbalanced, necessitating careful consideration as to which should be employed. The danger from reflex inhibition, producing primary syncope, is less liable to occur than when chloroform is used, and can be best treated by pushing the anæsthetic, unless this is contraindicated. Thus, even with the so considered safer and more fashionable anæsthetic, the supersaturation of the blood and nervous tissues, with its sequence of paralyzed respiratory and cardiac action, is a possibility not to be lost sight of.

When one considers that the aim and result of all anæsthetic procedures is to paralyze nerve-cell function, it must not be forgotten that the distance is not far to paralyzed centres, which portends so much. In all anæsthesias, whatever substance is used, the true anæsthetist strives to remain in that narrow limit between reflex inhibitory influences and paralyzed nerve centres.

68 West Tenth Street.

THE PATHOLOGY OF EVOLUTION.

By CORA HOSMER FLAGG, M.D.,

Since biology no longer places man in a separate order by himself but considers him as the last link in the long chain of organism, it has become absolutely necessary for a broad and progressive knowledge of man's structure, its physiology and pathology, that our medical schools should present these subjects from a comparative standpoint.

The great progress made in anatomy during the last few years has been wholly due to the study of the evolution of organs and tissues through lower to higher forms. Thanks to the work of those great masters of comparative anatomy—Wiedersheim, Cunningham, Osborn, Sutton, Wilson, Cope, Howes, Humphry, Rathke, and a host of others—this subject is at the present time the most progressive of all the biological sciences.

It now remains for physiology and pathology, based as they necessarily are upon morphological data, to profit by the consideration of the possibilities of comparative anatomy for elucidating many of the pathological conditions to which man is subject.

It is a common idea that the human body is fixed or stable in its structure, that it is perfectly and marvellously adapted to supposed uses for definite ends, while all the evidences from comparative anatomy, embryology, and physiology go to show that the majority of our organs are combinations, rearrangements, and compromises necessitated by the accidents of growing complexities. These same biological sciences show many indications that changes in man's organism are still continuing, and, by pointing out to us the centres of most rapid evolution, give us a hint as to what the man of the future will be like.

Much of this instability of structure is directly due to the mechanics of the upright position and to the fact that the body with its quadrupedal ancestry has not yet become perfectly adapted to this condition. Every region of the body shows evidences of this maladaptation. Some structures are in a state of progression—that is, they are tending toward more perfect adaptation; others are slowly retrogressing, some having gone so far in this direction as to have dropped out of use entirely, remaining now as vestiges. Some have disappeared, only to reappear as reversions or anomalies. Our developing, degenerating, rudimentary, and reversional organs show conclusively that man is now in active process of evolution.

It is the purpose of this paper to place in view the relations which exist between maladaptation and certain pathological conditions of various structures of the human body, or rather some diseases or pathological processes that are most obviously due to the fact that man has evolved from lower conditions of organism.

Naturally we should expect to find in the pelvis marked modifications adaptative to the upright position, for instead of a pelvis which transmits the weight of the posterior end of the spinal column merely to the femora, we now have a pelvis which transmits the weight of the whole column and upper extremities, and supports the weight of the viscera. In conformity to this change of function, instead of the "box-shaped" pelvis of the quadruped, with its long, narrow, straight ilia, straight sacrum with no projecting promontory, and straight birth canal, we have a "bowl-shaped" pelvis with wide-flaring ilia and contracted inlet, curved sacrum with projecting promontory, and a curved birth canal. It should be noticed that this latter type of pelvis is not found in the newborn infant, but commences to take shape as soon as the child becomes accustomed to the upright gait, and it increases in this direction as long as the plasticity of the bones allows. Litzmann finds that the European infant at birth has a pelvis much like that of the lower mammals, *i.e.*, the cavity is deeper, the sacrum scarcely curved, and there is more inclination of the pelvis, so that the entrance to it is round and large, differing much from the later adult form. This infant pelvis is as good evidence as to the shape of the pelvis in the early mammalian stage of human phylogeny as the gill slits are to the ichthyoid stage. The adult pelvis, while better adapted for support, is not the shape best adapted for easy and safe parturition. The curved birth canal, together with the changed angle of pelvic inclination, causes the canal to vary at different depths, making necessary a series of changes of position of the child's head during delivery. The projecting sacral promontory, most marked in civilized races, still further lessens the dimensions of the pelvic inlet. All these characters increase the danger to life during delivery of both mother and child, and it is well known that the death of thousands of mothers and children, otherwise perfectly healthy and well formed, can be traced to this evolutionary factor alone.

The highest expression of modification is found in the pelvis of the civilized woman. In her we have well illustrated the struggle that has been and still is going on between expanding ilia and contracting inlet for better support on the one hand, and the increasing size of the child's head, which is correlated with an increased capacity for brain development, on the other. It is of significance to note in this connection that the pressure of the viscera upon the pelvis is artificially increased by the corset-wearing habit. The civilized races are more or less mixed races, and so there is a constant discrepancy between the shape of the child's head and the shape of the pelvic inlet of the mother, which increases the difficulty of parturition. Primitive races are usually homogeneous races, and the shape of the fœtal cranium and the maternal pelvis are usually well correlated, hence we rarely find such difficult parturition arising from this cause among them. The pelvic contents of the other mammals and the human infant are not the same as those of adult man. A downward shifting of the viscera occurs when the child begins to walk, and the protruding abdomen, so like that of the anthropoids, disappears. The urinary bladder and its appendages, uterus, vagina, and their appendages, vesiculæ seminales, rectum, sigmoid flexure, and lower part of the ileum, are all pelvic organs of the adult man. In the other mammals and the human infant the sigmoid flexure, lower part of the ileum, and fundi of the bladder and uterus are always in the abdomen. No other reason can be assigned for this downward shifting except gravity; hence any pathological condition arising from their presence within the pelvis must be due to the upright position. Of the pelvic organs affected by downward pressure, the uterus probably suffers most. The various folds of peritoneum, so-called ligaments, and the round ligaments, while distinctly functional in the quadrupedal position, to act as "guy ropes," to prevent the gravid uterus from falling too far forward and interfering with the function of lungs and heart, practically do not support the uterus in the upright position. Adaptative changes have taken place in a measure in the tissues about the cervix uteri, the health and tonicity of which will be more generally recognized by gynæcologists as important agents in preserving uterine position. The inadequacy of this makeshift, however, is shown by the very great frequency of uterine displacements, which, together with the very serious disturbances accompanying them, furnish one of the most obvious pathologies of evolution.

Man is the only animal that fully extends the thigh

at the hip-joint. This straightening of the legs when the child begins to walk is effected by the development of a lumbar curvature in the spinal column. This convexity forward in the lumbar region has received much attention from comparative anatomists, many of whom claimed it as a distinctive human characteristic until Cunningham demonstrated a beginning development of it in certain of the semi-erect anthropoids. It is never found in the spines of animals habitually quadrupedal in gait. A cervical convexity also appears when the human infant acquires strength to raise its head and balance it on the summit of the spinal column.

The single, large, dorsally directed curve of the quadrupedal spine has been modified to the requirements of the upright position by the formation of these two antagonizing curves, and the massive development of the erector-spinæ group of muscles. Wiedersheim finds evidences of its present evolution toward more perfect adaptation in the increase of all of its curvatures, especially the lumbar, the shortening of the centra of the lumbar vertebræ, and the upward shifting of the pelvis on the column, which is shown by finding the fifth lumbar vertebra in all stages of progression toward becoming incorporated into the sacrum. Undoubtedly there was a point in man's phylum when the spinal cord accompanied the whole length of the column, which was much longer than at present, the coccyx being the vestigial representative of this shortening. An atrophy of the cord upward has taken place, and now it reaches only to the first lumbar vertebra. In view of this fact the attention is directed to the relation between those tabetic affections to which this part of the cord is subject and this upward degeneration.

There are evidences that the upper part of the spine possessed more ribs than at present, for a proof of the existence of cervical ribs in mammals is found in the Edentata. The seventh and sometimes the sixth cervical vertebra of the human embryo almost always possesses vestiges of ribs, and cases are not at all rare in which a seventh cervical sternal rib has been found in adult man. Sometimes it is paired, and often it does not reach the sternum. Often the first pair of thoracic ribs show such marked degenerative characteristics that Howes says "the question might be raised whether this tendency toward reduction at the upper end of the thorax may not be a determining factor in the degeneration so frequently found to be commencing at the apices of the lungs."

Since the upright gait frees our anterior limbs from the supporting and walking function—a function necessarily demanding equal use of the limbs of both sides—we have acquired right-handedness, no satisfactory explanation of which has as yet been suggested. Whatever the cause, there is associated with it an inequality of muscular development between the two sides. This inequality of muscular development may be assigned as one of the causes of lateral spinal curvature, a pathological condition found only in man.

In the lower mammals the fibula is nearly equal in size to the tibia, and both articulate with the femur, contributing to the formation of the knee-joint. We find this same condition of the two bones in the human embryo at one period of its development.

In the upright position during phylogenetic development the weight of the body has come to rest on the tibia alone, and the fibula has shifted downward and dwindled to a mere appendage, saved, however, from still further degeneration by its connection with the heads of the peronei and the part it takes in the formation of the ankle. It is not strongly functional; hence it is a weak structure, and, being in a position exposed to strains and impacts, is very frequently fractured.

Fractures of the neck of the femur are probably rendered more frequent from the fact that the angle it makes with the shaft of the bone is increased by the weight of the body as age advances.

While the viscera as a whole were nearly as well adapted for use in an upright position as in a horizontal one, yet the change to verticality did bring about certain disadvantageous conditions, aside from those resulting from pressure, which have caused pathological conditions. Clevenger has shown that in the quadrupedal position the circulation in the intercostal and lumbar veins has to be maintained against gravity; consequently we find in them an abundant supply of valves. In the upright position the direction of the blood current in these veins is horizontal, and, although valves are of no functional value, yet they are always present in various stages of retrogression. This interesting phylogenetic fact is still more emphasized by our finding many more valves in the human embryo than attain to complete development in the later adult form. While there is no reason for valves in the horizontally disposed portal system of the quadruped, their absence in the hemorrhoidal and other parts of our portal system has an important influence on the development of certain diseases due to congestion, one of the most common of which is hemorrhoids or piles. Much suffering is caused also by the frequent absence of valves in the ovarian veins, especially in the vein of the left side, which almost never possesses a valve.

The heart works at a great disadvantage, because it has to force the blood column to a higher level and against greater hydrostatic pressure. We might find here a cause for the tendency to heart affections from which man suffers. The difficulty of lifting the blood column against gravity is shown by the frequent occurrence of varicose veins, varicocele, etc.; and as disorders secondary to heart affections we have anasarca, congestions of the liver, ascites, cardiac dropsy, etc.

The upright position has exposed the great vessels of the leg and arm, increasing the danger to fatal hemorrhages from their greater liability to injury.

The cæcum and colon are not favorably located in the upright position for carrying off fæcal matter; and the rectum, forced to follow the curve of the sacrum by pressure of other organs, is because of this the seat of numerous ills.

The weakest spots in the abdominal walls are those openings in the abdominal muscles just above Poupart's ligaments for the transmission of certain structures from the abdominal cavity. When the visceral stress is in the ventral direction, this weak part is in a protected position; but with visceral stress in the caudal direction these weak places are most unfavorably located. Adaptative modifications of tissues about the inguinal canals have taken place, but when the abdominal muscles are powerfully actuated they are often strained, the openings enlarged, and the intestine is forced out, constituting the pathological condition known as inguinal hernia.

Every region of the body shows some record of the past history of the race, in the large number of vestigial structures, the present representatives of parts once of value when environmental conditions were different from what they are now. These vestiges through lack of function and consequent lessened metabolism become more quickly overloaded with the katastates of their own cell life, and so fall the more readily a prey to adverse conditions. So great is their liability to be attacked by disease that "an unused part is a diseased part" has become a medical axiom.

Many obsolete canals which were functional in our remote ancestors, instead of filling up and becoming cords, have sometimes a lumen left in them, which occasionally fills with fluid, making tumors. Many

of the ducts and organs connected with the genito-urinary apparatus, being tertiary adaptations from a primitive kidney system, through a secondary kidney system, are peculiarly liable to disease, not only on account of their late and complex evolution, but from the persistence of many vestigial structures connected with them. The parovarium is one of these—the remains of the Wolffian body. It consists of a series of short vertical tubes, dipping into the hilum of the ovary and ending blindy above in a duct. From some cause these tubes are often the seat of cysts which may attain great size. They are sometimes accompanied by ascites, sometimes infect the peritoneum, and often cause death by malignant degeneration.

Because an organ in a pathological condition may cause widespread systemic derangement is no proof that such an organ is now of physiological value, when there is no other evidence as to its function. The fact that the thyroid gland, when diseased, may give rise to goitre, acromegalia, and other systemic disturbances, is no proof that the thyroid in health is of functional value, and that it should not be classed as a vestigial organ.

Not enough of experiments have been made as yet of removal of the thyroid, unaccompanied by other conditions, to give us data as to any normal function. What has just been said is also applicable to the thymus gland and the suprarenal capsules.

In many places where canals open on a free surface, the orifices are usually surrounded with glands and a mass of adenoid tissue. The tonsils are an example of this, located in the fauces and marking the inner orifices of the gill slits. There is a third tonsil, identical in structure with the tonsils of the fauces, in the pharyngeal vault, which, although not associated with a gill slit, is situated at the pharyngeal orifice of a duct, which in the embryo traverses the floor of the pituitary fossa and opens into the roof of the pharynx. These are very troublesome vestiges, often giving rise to tonsillitis and malignant tumors, and from their vestigial character are the seat of the initial lesion in many pathological affections of the throat. As is well known, adenoid tissue has an inherent tendency at slight provocation to increased activity of its cellular elements, thus enlarging the mass; and it is this hypertrophy, especially of the third tonsil, that causes so much trouble in childhood.

It has been conclusively shown that the intestinal cæcum, owing to changes in diet and habits, has become much shortened in man—the vermiform appendix being left as a rudiment of this shortened part. It has all the characteristics of a rudiment, noticeably variability in both length and occlusion, and a greater development in the embryo than in the adult. Appendicitis is now a well-recognized lesion, and to it other inflammatory conditions, as the different forms of typhlitis and peritonitis, can be traced.

All of that great number of our retrogressive and progressive structures which are now becoming changed to secondary uses, or becoming more highly differentiated by the modification of their cell habits, offer a less vigorous resistance and more readily succumb to disease than do those structures that have developed along one line alone, so retaining their earlier cell habits in constant vigorous activity.

While congenital abnormalities are usually the result of local disturbances or malnutrition, they are usually of a type recalling the original evolution of that part; so that local disturbances seem to be more effective on an atavistic line. We have cleft palate from failure of the maxillary plates of the first gill arch to approximate; anterior cleft palate and harelip from a failure of the frontal process to project sufficiently far downward; supernumerary auricles and branchial fistulæ at the gill-slit localities from arrested developmental processes; hypospadias from failure of the genital furrow to unite in the male.

It is a noticeable fact that the most common brain lesions are those of the latest developed and most highly specialized convolutions; that the rarest lesions are those affecting the deeper parts of the brain, where lie the primal emotions and desires common to nearly all animal life.

The external parts of the brain, which during the course of evolution have developed and specialized in response to individual need, rather than of species necessity, are the most complex and hence the most unstable parts. Consequently we find them the most liable to disease and the most easily disturbed by disease in other parts of the body. The more complex parts of the brain are associated with the more complex phenomena of the mind, such as the more intricate correlations from which arise generalizations of concrete experiences, and hence deductions as to the nature of new but analogous conditions. These complex functions, being the latest acquired, are the most easily disturbed, and their derangement furnishes the most satisfactory explanation of delusions, double personality, and other morbid mental manifestations. The insane will readily commit suicide, as the primitive savage will readily sacrifice his life, but both will instinctively struggle against another injuring them in the same way. The appreciation of value of one's own life to one's self is a later acquirement—the struggle for existence against another being a primal tendency. In those brain lesions of the cortex which produce insanities, the deep-seated primal emotions are freed from the repression which this part of the brain has gradually, during the course of evolution, come to exercise over them.

Between these two extremes of primal emotions and complex correlations there lie the vast series of ever-specializing centres of organic and muscular activities. The lesions in these centres, in the frequency of their occurrence, lie between the comparative lack of them in the case of the deep-seated parts of the brain, and the constant occurrence of them in the later, higher psychic development of the external portions.

In this cursory review of pathological conditions due to the evolutionary nature of man's origin, we have only touched upon those which have the most clearly arisen from the action of this principle in him. Broadly speaking, however, the pathologies of evolution should not be thus confined; for in the broader view, which takes in the action of this principle throughout nature, we should include within our inquiry all factors that affect man.

Before we are prepared fully to understand the details of pathology, they must be carefully verified and collated under a broad system of comparative study, which not only takes into account the individual disease as it now exists, but which will trace, as far as possible, the factors in the long history of our growth that gave rise to it and from which it too has evolved.

The Treatment of Chorea.—Dr. De Renzi has confidence in only three remedies: 1. Absolute rest, avoiding any external excitation whatever, and placing the patient in a dark room. 2. The ascending electric current along the spinal cord—the best results with a gentle current, progressively increased. 3. Arsenic in large doses, commencing with twenty drops of Fowler's solution each day for children, and double this amount for adults. When the chorea ceases the medicine should be continued, for the disease returns readily. The nutrition of the patient must be maintained, and good food and gymnastics are useful.—*Gazzetta degli Ospedali e delle Cliniche.*

TOBACCO AMBLYOPIA.

BY RICHARD ELLIS, M.D.,

A CHRONIC retrobulbar neuritis may arise from a variety of causes, chief of which is the abuse of tobacco. From its most common cause the disease has been called "tobacco amblyopia," though it is better to keep the term "retro-bulbar neuritis" as derived from the pathology, rather than to accept a name derived from the etiology. The victim usually comes early to the physician, complaining of some loss of sight with possibly a slight cloudiness obscuring vision. In such cases the ophthalmoscope reveals no signs of a special pathological state, and normal vision soon returns on the discontinuance of the use of tobacco.

In advanced cases, vision may range from $\frac{20}{200}$ to $\frac{5}{200}$. Reading is impossible; a hazy cloud is extremely annoying; central vision is so poor that mechanically the patient will turn his head to either side in order to use the peripheral parts of the retina. He is often sure he sees better at night, at least he does not see this haziness quite so disagreeably. This oft-observed nyctalopia caused Arlt, ignorant of the pathology, to call this form of neuritis "retinitis nyctalopica." The patient does not know when the trouble began. He may early detect his inability to read as well as formerly, but many of these patients (who read but little) are not troubled much until failing vision interferes with their work. Then some consult the physician at once; others, not realizing the trouble, lose their positions, and console themselves with their beloved pipes and coddle their cud until a condition of almost complete blindness drives them to some hospital to seek advice.

The patient tells enough to suggest at once the diagnosis. If the ophthalmoscopic examination is negative, the physician examines for central color scotomata in that part of the field corresponding to the part of the retina supplied by the papillo-macular bundle of the optic nerve. A careful examination will show a color scotoma in both eyes, with loss of central vision. As the retina is very easily exhausted, especially at the border lines of the scotomata, it is not advisable to try to map out the boundary lines too carefully. Have the patient look at a black lead pencil a few feet in front of him, and then quickly present to the nasal field of the eye examined a small black disc with a red centre. At once the patient recognizes the color. When the disc is brought to the temporal side, the patient cannot possibly recognize the color in the oval field corresponding to the maculo-papillary retinal region, or in mild cases he will at once notice that the color is less bright. In advanced cases he may not recognize bright blue or even white.

The peripheral parts of the field are color blind in the normal eye. The nearer the color approaches the centre of the field, the more acutely is the color recognized. In this form of amblyopia, since there is an atrophy of the very nerve fibres that best distinguish colors, we expect the patient to have central color scotomata and should remember this as the leading point for diagnosis in this form of amblyopia.

The ophthalmoscopic examination is usually negative. From a close examination the physician is usually convinced (from the breath) that most of these patients indulge in the abuse of whiskey as well as in that of tobacco, so that in many cases it is a question which should take the greater blame. I am convinced from the pathology of the abuse of alcohol (increase of connective tissue, decrease of normal cells) as well as from the breath, that alcohol must be considered as an adjuvant to the tobacco in such cases. Some believe that alcohol alone can produce this retrobulbar neuritis. Noyes states in his text-book that "in alcoholic amblyopia we find usually a dull red nerve with swollen veins, rather hazy borders, and torpid circulation. Atrophy may subsequently ensue. . . . In tobacco amblyopia the nerve is brighter and more nearly normal, or it may show tokens of atrophy or of interstitial inflammatory exudation. Generally there is little lesion to be recognized."

Since Samelsohn showed that the pathology of this form of amblyopia lies in the maculo-papillar bundle within the optic canal, we look closely at that part of the fundus which is supplied by this bundle of nerve fibres. We are not surprised to find the temporal side of the nerve whiter than the rest of the nerve, so white in some cases as to indicate atrophy and to cause surprise that this peculiarity has not been more particularly mentioned.

The workingman living out of doors, and consuming tremendous quantities of food and oxygen as well as tobacco, is usually the victim. The cigarette smoker escapes because his stomach gives out before his optic nerve is in the least danger. Were the "gentleman" smoker to consume the quality and the quantity of tobacco that some of our workingmen smoke with keen pleasure, the result would be an attack of acute nicotine poisoning.

I personally am very fond of tobacco, but a few whiffs from a hod carrier's vademecum would satisfy my tobacco craving, at least until after dinner. There is more nicotine-paralyzing ability in the smoke from one pipeful of black "juicy" tobacco than in a hundred mild cigarettes, yet occasionally we hear of mild amblyopia from cigarette smoking. Were the workingman to use milder tobacco and to clean out his pipe occasionally, this form of amblyopia would rarely be seen; but so long as the strongest kinds of tobacco are sought for and enjoyed, so long will tobacco amblyopia be encountered. A patient recently seen at the Sherwood Eye Infirmary, in the service of Dr. Scott, was a stalwart Bohemian, who had been gradually growing blind. His friends kindly diagnosed his trouble as due to "advancing years." He acquiesced in the diagnosis, and, losing his position as a stonecutter, he engaged in the occupation of keeping his pipe warm, until his sight was almost gone, when he wisely thought it time to consult a physician to have his friends' diagnosis verified. He was surprised to learn the true diagnosis and promised to give up smoking at once. Two weeks later he proudly stated he had not smoked in this time, but found "chewing about as satisfactory." He was as innocent of any wrong doing as a former patient who promised to smoke "less often," and a month later showed me his pipe, which he proudly stated he smoked but "three times a day." It was made to order and about the size of a beer keg. The ophthalmoscopic examination of this Bohemian patient was negative save for the whiteness of the temporal side of the disc, which was so very white as to suggest atrophy at once. Vision of right eye, $\frac{10}{200}$; left eye, $\frac{5}{200}$; white square on black background scarcely seen in field where red and blue scotomata were clearly made out. Colors easily distinguished on nasal side. The patient chiefly complains of loss of central vision and blurring of vision. He says he sees better at night and turns his head to either side in order more clearly to see a light in front. The patient has been soaked in nicotine so long that a bad prognosis is given, though the majority of cases improve if tobacco is stopped and strychnine is prescribed. I have seen a case regain $\frac{20}{20}$ from $\frac{20}{40}$ in a few weeks; $\frac{20}{20}$ may be regained from $\frac{20}{40}$ in a comparatively short time, but $\frac{5}{200}$ sight is so very poor as to make the prognosis very unfavorable. Certainly the white atrophic appearance of the temporal region of

the disc makes one realize that the nerve has really been poisoned to death.

Though we do not know why these special fibres of the optic nerve should be affected, we do know that this great manly fellow has lost much of his sight through ignorance, and his family has lost the blessing of his support.

It is indeed a pity that the average man does not realize the danger that lurks in this seductive weed. Like a siren, the charming Nicotina soothes her victim while she slowly but cruelly blinds him. Accursed be such a siren, and accursed again I say, as I see this great fellow blind and his family in want! Such a siren should be exposed as she lies on the watch, concealed by the ignorance of those most in danger—the abusers of tobacco. The use of tobacco is indeed a great "comfort." It satisfies a craving so well that perhaps a majority of the inhabitants of the world worships at the throne of Nicotina. Of nothing else is this true excepting alcohol. If the real value of tobacco among all classes of men, especially the workingman, the soldier, and the sailor, could be estimated, it would be found to be of more value than all the nuggets of the Klondike. Certainly it has been truthfully and well said that "tobacco is a lone man's companion, a bachelor's friend, a hungry man's food, a sad man's cordial, a wakeful man's sleep, and a chilly man's fire."

We know tobacco is a powerful poison, yet we believe in its use. The two things most desired by the out-of-doors man are tobacco and coffee, and of these two, tobacco always comes first. He who has never enjoyed an after-dinner cigar will not be in sympathy possibly with those using tobacco, yet he will agree that the use of tobacco cannot be stopped, and that it is the abuse that injures, not the use of tobacco. He will agree with the writer that only men should use tobacco, and they only with intelligent moderation, proceeding from a knowledge of the dangers as well as the pleasures concealed in the world-worshipped yet poisonous weed.

Progress of Medical Science.

Nasal Micro-Organisms.—1. In all bacterioscopic investigations of the nasal fossæ, in all researches as to the action of nasal mucus, etc., a clear distinction must be made between the vestibule of the nose and the proper mucous cavity. The former is lined with skin, and is not part of the nose cavity proper, but only leads to it. 2. Contamination with the lining of the vestibule is difficult to avoid, even when this source of error has been realized. 3. In the dust and crusts of mucus and *débris* deposited among the vibrissæ of healthy subjects micro-organisms are never absent, and are usually abundant. 4. On the Schneiderian membrane the reverse is the case. Under normal conditions micro-organisms are never plentiful here, are rarely even numerous, and in more than eighty per cent. of cases no organisms whatever are found and the mucus is completely sterile. 5. The occurrence of pathogenic organisms must be so infrequent that their presence on the Schneiderian membrane can be regarded only as quite exceptional.—Thompson *and* Hewlett, *Arch. of Otol.*, xxiv., 3 and 4.

The Bacteriology of Typhoid Fever.—In the course of observations made in eighty-three cases of typhoid fever, Besson (*Revue de Médecine*, June 10, 1897) found albumin in the urine in forty-seven. Bacteriologic examination of the urine in thirty-three of these disclosed the presence of typhoid bacilli in six, principally in those in which the albuminuria was pronounced. In none of the cases examined with this end in view, and these included especially those attended by complications, such as hemorrhage, phlebitis, and suppuration, were the bacilli found in the blood and but once in the contents of a rose spot. It is therefore believed that the cutaneous exanthem is of toxic origin. Of fourteen cases presenting angina, bacteriologic examination of material obtained from the tonsils disclosed the presence of typhoid bacilli in six. In thirty-three cases suppurative complications were apparently dependent upon the staphylococcus pyogenes and in five upon the streptococcus. Meningitis complicating one case and urethritis complicating another were found associated with the bacterium coli commune. The typhoid bacillus alone was found attending suppurative complications in six cases. From the foregoing observations the conclusion is reached that suppuration due to the typhoid bacillus is frequent in the course of typhoid fever. It is usually unattended by constitutional phenomena or febrile reaction; the temperature may even be subnormal. The complication is insidious in development and may require exploratory puncture for its detection. It develops most commonly during the period of defervescence or in convalescence and is usually benign in course, a fact that may be related to the phagocytic activity displayed by the pus.

The Relation between Tissue Change and the Leucocytes in Connection with Blood Dissolution.—As a result of observations in a case of malarial intermittent fever, supplemented by experimental studies in which blood dissolution in animals was effected in various ways, Kühnau (*Archiv für klinische Medicin*, vol. lviii., Nos. 4 and 5) found that such dissolution is attended by a considerable degree of leucocytosis, together with metabolic changes, as manifested by increased elimination of uric acid and xanthin bases; primary increase with secondary diminution in the elimination of phosphoric acid; and increased elimination of chlorides. The chlorides and the phosphoric acid appear to stand in vicarious relations with one another, the retention of the one corresponding with increased elimination of the other. The increased elimination of alloxur bodies is dependent principally upon destruction of the leucocytes. Probably other nucleated cellular elements take part in this process and in slight degree also the nuclein-containing albuminous constituents of disintegrated red blood cells. The mother substance for the formation of alloxur bodies is in large part contained in the plasma and the serum and in smaller degree in the red blood corpuscles. The amount of uric-acid-forming substance depends upon the number of leucocytes in the blood. Normal blood serum induces only a slight increase in the elimination of alloxur bodies and leucocytosis; typhoid serum none at all; and leukæmic serum a very considerable increase. The primary increase induced by leukæmic serum results from the presence of uric-acid-forming substances; the secondary increase is the result of the increased production and destruction of leucocytes dependent upon the activity of the leukæmic serum. The leucocytosis attending blood dissolution is an effect of the co-operation of three causes: (*a*) the direct leucotactic action of the blood poison; (*b*) the chemical substances (especially nucleins) set free as a result of the destruction of the cellular elements of the blood; (*c*) the remains of disintegrated blood corpuscles circulating in the blood. The leucocytosis induced by injection of corpuscular elements into the blood is a pure phagocytosis and leads to no notable destruction of leucocytes. The increased destruction of leucocytes in the blood in cases of infectious diseases is due to the presence of a leucocytolytic substance.

THE YELLOW-FEVER OUTLOOK.

THE situation in those parts of the South where yellow fever prevails remains at the present writing practically unchanged. New cases are reported daily in the towns where the disease gained an entrance before its true nature was recognized, but this is only what must be expected for some time to come, especially in view of the fact that in many of these places the sanitary conditions are far from being perfect. There is no cause, however, to fear a disastrous epidemic or a wide extension of the disease, for the health authorities are thoroughly alive to the gravity of the situation and may be relied upon to keep the fever practically confined to the localities where it now exists until cold weather shall set in.

The epidemic of fear which seized upon the entire population within a radius of five hundred miles, when the occurrence of yellow fever at Ocean Springs was first announced, seems to be gradually subsiding, although its influence is still seen in the shotgun quarantine which nearly every hamlet in Alabama and Mississippi has established against its neighbors. In some places there is a double line of shotguns, one at the outskirts of the town, guarding it against approach from the country, and the other a short distance outside of that, guarding the surrounding country from an invasion by the urban population. In the mean while in neither locality is there any fever, and the result of this senseless panic-inspired quarantine is to keep the community in a state of constant apprehension, to shut out the necessary supplies, and to put an end to all business. The sooner such baseless alarm as this subsides, the better it will be for the country at large as well as for the communities where it prevails. The fear exists chiefly in places where there is not the slightest danger of an outbreak, while in those where the disease actually prevails the situation is regarded with comparative calm.

The effective work of the Marine Hospital physicians and of the local boards of health is aided by the weather, which has become cool all over the country. Although no frosts can be expected on the Gulf Coast and the neighboring parts of the interior for some time, the temperature has nevertheless fallen sufficiently to exert a very favorable influence upon the course of the epidemic, if the mild prevalence of the disease at this time can be dignified with such a title. It is a fortunate circumstance that the disease appeared so late in the season, for, however well it might have been gotten under control, it would almost certainly have lingered in the large cities until the advent of cold weather, thus making them dangerous for unacclimated persons to visit. As it is, however, there are only a few weeks of warm weather remaining in which yellow fever is possible in those latitudes. According to Dr. Touatre, of New Orleans, the history of all previous outbreaks of yellow fever in that city shows that no epidemic, however severe, can long survive the cold that is sure to come in October. The great epidemics have always begun to wane with the first cold of that month, and have practically disappeared entirely in November. Several years are recalled in which the fever broke out in August or later, and was quickly killed by the frost before it had the opportunity to assume the proportions of an epidemic.

With the coming of frost and the disappearance of the fever the danger will not be over, however, for the frosts of an entire winter do not always destroy all the concealed germs of the disease. It will be a matter of general concern, therefore, that the places which have been invaded by yellow fever this year be thoroughly cleaned and put to rights during the winter, for unless the warning of the present visit is heeded some of the infected cities will very probably see a return of the disease with the first heats of summer. To trust to the efficiency of quarantine while neglecting local cleanliness, is to live in a fool's paradise.

THE MODERN TREND OF PHARMACY.

ANY one who will persue carefully the number of excellent papers read at the recent meeting of the American Pharmaceutical Association, will be impressed by the fact that legitimate pharmacy, both from scientific and business standpoints, is in a bad way.

Mr. William C. Alpers, the chairman of the scientific section of the association, in an able address on the "Modern Trend of Pharmacy," is quite emphatic in the declaration that the conscientious and scientific pharmacist of to-day is by no means a thriving and prosperous member of the business community. To give becoming emphasis to his position, he significantly repeats what very many of his confrères have said often enough before, that "Pharmacy has ceased to be a science; it is a mere trade, and a poor one at that." In this respect its twin sister, medicine, can give it due sympathy and meet it on common grounds of mutual condolence. Both sciences are threatened by the monopolistic tendencies of wholesale prescribers and wholesale manufacturers. What the hospital and dispensary abuse is to medical practice, such is the modern pharmaceutical plant with large capital and advertising push to the ordinary dispensing pharmacist.

In this connection Mr. Alpers significantly asks: "How many truly pharmaceutical laboratories con-

nected with the shops are there to-day? How many pharmacists can vouch for the correctness of their preparations because they made them? If we ask a young graduate from any of our pharmaceutical colleges whether he prepares his own potassium iodide or iron sulphate, he will probably consider us jokers; and yet there are old pharmacists now living who were taught to prepare their chemicals themselves and who actually did so in their younger years."

While this state of affairs may interfere in a great measure with shop preparation of different compounds, it is nevertheless the fact that the large manufacturers can afford to make and sell their products much cheaper than a retailer who cannot buy expensive machinery and who has not the necessary capital for competition in an open market. For purely business reasons there is hardly any other argument to be offered than that which applies to the survival of the fittest. It has come to pass, then, that the competent retail compounder cannot compete with the equally conscientious wholesale manufacturer. This, however, does not interfere with the retail pharmacists being the recognized dispensers of such cheapened articles. But there are many other troubles in the way, as duly noted by different members at the meeting in question.

It is claimed with reasonable show of truth that the doctors and apothecaries too often cross forbidden lines in relative interpretation of privileges. The doctors, for instance, are given to dispensing their own medicines; while, on the other hand, the apothecaries are constantly indulging in counter prescribing. The bone of contention is held at either end by the opposing parties, while the real meat is in the middle. Each to get the whole is pulling with all his might in different directions.

The remedy suggested by one writer, Dr. F. E. Stewart, who is both M.D. and Ph.G., is that the apothecary split the difference by prescribing for minor cases and be legally qualified to do so. This is claimed to be the remedy for increasing the prescription business, while it would not seriously harm the doctor. The apothecary would be sure to sell some medicine, when the doctor would not be likely to see the patient at all. Thus it is tacitly admitted that the doctors and druggists are natural rivals, and, taking a pharmaceutical view of the situation, the house is divided against itself. While the respective parties muse the fire burns, and the innocent cause of the trouble—the patient himself—either buys his drug without question, prescribing for himself, or becomes the easy dupe of the advertising quack. The doctor, to keep what patients he has, gives medicines with his advice; and the apothecary ekes out extra profits by selling tooth picks, hair brushes, and perfumery. Thus it appears that both professions are degenerating into the merest trades, and are forced to deplore the lamentable existence of a cut-throat competition.

Contagion and Prison Discipline.—The lockstep has been abolished at the Detroit house of correction because it was thought to facilitate the spread of contagion.

THE MILK PHILANTHROPIST AND THE HEALTH BOARD.

The health board has scored a mild sensation by securing the technical conviction of a well-known and well-meaning philanthropist, on the charge of selling a specimen of milk below the claimed nutritive standard. In the testimony for the prosecution it was stated by the inspector that "the sample from one can, when analyzed by the chemist for the health department, was found to be a trifle below the required standard." On the contrary, it was also admitted that the methods of sterilization adopted by Mr. Straus, the defendant in question, had been formally approved by the board, that the milk at other depots had been found to be of excellent quality, and was far above the legal standard. Even the justice, in passing sentence on what he acknowledged was merely technical grounds, was impelled to apologize for his decision, and took occasion to compliment the alleged culprit on the truly laudable motives of his enterprise. The motives of the health board were apparently not under discussion, save in the very paradoxical assertion that the said board had no desire to cast any reflections on the work or to hinder it in any way. It is somewhat difficult to understand, in view of the latter assertion, why legal proceedings should have been instituted because of a single accident or oversight, when a more prompt remedy could have been found by notifying the proprietor, who would doubtless have been only too glad to remedy the difficulty. It would appear to be a matter in which strictly legal right on the part of the board should have been tempered with a little discretionary mercy. The board has immense powers under the law, but it cannot be too circumspect in using them. Above all, it should be particularly careful to guard against all suspicion of persecution. In spite of the verdict, the public will not believe that the good citizen is really guilty of any culpable wrong, while the board will miss much of the credit which might have belonged to a well-considered action.

ORIGIN OF THE VERTEBRATES.

Despite the many strides made in recent years—more particularly in chemistry, biology, and astronomy—it may be doubted whether the problems of the origin of life are much nearer their solution; in truth, so many fresh facts have been accumulated and so many new sources of discovery have been opened, that in many ways we would seem to be in more of a fog than before. That Darwin has not said the last word in regard to evolution is certain. Dr. Stuart Jenkin, of Sudbury, Ontario, proposes to explain man and the other vertebrates by the theory of parasitism. There is, he thinks, but "one theory which seems adequately to explain these hitherto obscure points; and it is this—that the vertebrate organism, instead of being a single organism which has been evolved from a simple to its present highly complex form by a gradual and cumulative differentiation, is, in fact, a compound made up of two distinct organisms constantly associ-

ated. In other words, that the divergence of the vertebrates from the lower type was caused by the parasitic implantation of one organism of the ganglionic type upon another, the implanted organism giving rise to the cerebro-spinal nerve system and internal skeleton. More than this, I am convinced that the ganglionic type is itself a compound, the ganglions being parasitic on a simple cellular matrix."

The paper explaining these views was first published in the *Medical Age*, and has been issued as a reprint. Dr. Jenkins' theory cannot be said to be lacking in ingenuity, whatever else may be thought of it.

News of the Week.

Hospital Ships.—The Red Cross Society of Japan has given orders, it is said, for the construction of two thoroughly appointed floating hospitals, of twenty-six hundred tons each, for the treatment of the wounded in time of war. The good accomplished by the hospital ships during the war between Greece and Turkey is said to have been the inspiration for this move on the part of the Japanese Red Cross.

The Women's Medical School in St. Petersburg.—The first course has begun in this new school for women, with a class of one hundred and sixty students, nearly an equal number of applicants having been refused admission for want of room. It was at first determined that only orthodox Christians should be admitted to the school, but a recent ukase had modified this to the extent that women other than Christians may be received, provided the number of them shall not exceed five per cent. of the total. There are accordingly eight such in the first class, so many having applied that the full complement allowed by law was admitted. They are obliged to pursue the same course of studies as their orthodox sisters, and this includes the study for six months of dogmatic theology. The other subjects for the first year are anatomy, histology, physiology, botany, and chemistry.

Rheumatism a Form of Pyæmia.—Dr. Singer, of Vienna, asserts that acute articular rheumatism is due to the presence of pus microbes in the tissues, and that it is therefore a modified form of pyæmia. Following out this theory, he believes that the true specific treatment of the disease consists in the intravenous injection of a sublimate solution, and he claims that this will cut short the disease and prevent valvular complications much more effectually than salicin or salicylic acid. His experiments and investigations were conducted in Weichselbaum's clinic.

Bowery Liquor.—The health board of this city has been making an analysis of the beer and whiskey sold in the "dead-houses" for three cents a glass. The beer was said to be of good quality, containing only hop bitters, and no injurious adulterants were found. The whiskey was artificial in almost every sample analyzed, being made from cologne spirits (containing about fifty per cent. of alcohol by volume), colored by caramel, and flavored by a small amount of a non-injurious essence. In the chemist's report it was said that this made whiskey is probably less injurious to the system than a genuine new whiskey of the same alcoholic strength, containing twenty-five per cent. or over of fusel oil. The proportion of alcohol in the diluted stuff sold for three cents an ounce was only about sixteen per cent.

Sir William Gowers has been elected an honorary member of the Russian Medical Society of St. Petersburg. This society was established in 1833, and is one of the oldest medical associations in Russia. Professor Popoff, of the Imperial Military Medical School, was elected president of the society at the beginning of the present year.

The American Public Health Association.—The coming meeting of this association in Philadelphia, from October 26th to 29th, will be the silver anniversary of the association, and the attendance and the number of papers read will probably be larger than at any previous meeting. A feature of the meeting will be an exhibit of hygienic and sanitary appliances, preparations, etc., including all articles capable of furthering or preserving public or personal health.

New York State Association of Railway Surgeons.—The seventh annual meeting of this association will be held at the Academy of Medicine, New York City, on Tuesday, November 16, 1897, under the presidency of Dr. J. Frank Valentine, the chief surgeon of the Long Island Railway. Dr. C. B. Herrick, of Troy, is the secretary of the association.

A Great Medical Journal.—The London *Lancet* for August 21, 1897 (students' number), consists of eighty pages of text and one hundred and forty-four pages of advertisements—in all, two hundred and twenty-four pages. It is said to have a subscription circulation of twenty thousand copies a week.

Dr. Stephen Smith has been appointed by Mayor Strong a charities commissioner, to succeed Mr. Silas C. Croft, who has been appointed to a federal office. Dr. Smith has been a member of the State Charities Aid Association, and is thoroughly familiar with the work of the charities department.

Delaware County (Pa.) Medical Society.—The regular monthly meeting of this society was held at Chester, Pa., on September 10th. Dr. E. Marshall Harvey, of Media, read a paper on "Cholera Infantum"; Dr. Frank J. Evans, of Chester, one on "Milk"; and Dr. J. F. Forwood exhibited a fibrocystic tumor.

"The Zoological Bulletin" is the title of a new journal, issued as a companion to the *Journal of Morphology*, designed for shorter contributions in animal morphology and general biology. It is published by Ginn and Company, under the editorial supervison of C. O. Whitman and W. M. Wheeler, of the University of Chicago. The first number, that for August, 1897, contains articles on "The Morphology of the Petrosal Bone and of the Sphenoidal Region of the Skull of

Amia Calva," by Edward Phelps Allis, Jr.; "Recent Experiments on Regeneration," by Charles W. Hargitt; "The Metamerism of Nephelis: A Contribution to the Morphology of the Nervous System, together with a Description of Nephelis Lateralis," by Charles Lawrence Bristol; and "Remarks on the Question of Intercalation of Vertebræ," by G. Bauer.

To Further Woman's Health.—A lady in St. Petersburg, Mme. Woltov, has in hand the establishment of a new club or association, the sole object of which is to be the hygienic development of women. The Tsaritsa is said to approve heartily of the project and to have lent it the aid of her influence.

Dr. S. Henry Dessau has resigned his position as chief of clinic to the children's department, Mt. Sinai Hospital Dispensary. In a letter from the chairman of the dispensary committee, Dr. Dessau's resignation was accepted with expressions of appreciation of his faithful services.

Navy Department, Bureau of Medicine and Surgery, Washington, D. C.—Changes in the medical corps of the United States navy for the week ending September 18, 1897. September 16th.—Assistant Surgeon H. La Motte was placed on the retired list, September 15th, for physical disability.

The Victorian Order of Nurses. — Notwithstanding the vote of the British Medical Association in favor of this scheme, the medical profession in Canada does not support it with much enthusiasm. The *Canadian Medical Review* says that it thought the movement was dead, but it would seem that there is still a little vitality in the cause, or rather a little sympathy for it in its moribund condition. At the meeting of the British Medical Association, Dr. Roddick moved that the scheme be approved, and in courtesy to him, our contemporary says, the motion was allowed to pass. But it adds that "the Ontario Medical Council, the Ontario Medical Association, many smaller medical societies, many medical men, and especially those in Manitoba, have expressed themselves as opposed to the whole scheme. These should know better than our British visitors. This resolution of the British Medical Association may let the affair down easily, by showing that some at least sympathized."

Drinking in England.—The report of the inspector of inebriate asylums in England, which has just been issued, states that drunkenness is increasing not only among the poor, but also among the upper classes, and especially among women of all classes. Out of 442 male inebriates treated at the Dalrymple Home and discharged as cured, 101 were university men, and 316 of the remainder were well educated; 235 were married, and the others were widowers or bachelors. In 228 cases sociability was said to be the cause, ill-health caused the downfall in 36 cases, and overwork was given as the excuse for taking to drink in 32 cases. In fifty-five per cent. of the cases the excess was traceable to predisposing hereditary causes. About one-third of the cases treated are permanently cured. Out of the 442 patients discharged from the Dalrymple Home, 372 were kept trace of, and of these 149 were said to be entirely cured, 24 had improved, 164 had relapsed, 31 were dead, and 4 were insane.

The Westchester (N. Y.) County Medical Society.—The annual meeting of this society was held at New Rochelle on Tuesday, September 21st. Dr. Hermance delivered the presidential address. A paper on tuberculosis was read by Dr. Stubbert, of Liberty; and one on hysteria by Dr. Grainger, of Bronxville.

The Plague is reported to be increasing in the Bombay presidency. Several Europeans are among those who have been attacked at Poonah. A despatch to the London *Daily News* from Odessa says that the plague has broken out in the northern Caucasus. A sanitary commission has been sent from Tiflis to determine the nature of the disease prevailing there, and to take all necessary measures to prevent its spread in case it proves to be the bubonic plague.

Obituary Notes.—Dr. Samuel McNutt Ross died at Altoona, Pa., on September 13th, aged seventy-three years, in consequence of injuries received by being knocked down by a wagon. He was graduated from Jefferson Medical College in 1850, and had been engaged in the practice of medicine at Altoona since 1875.—Dr. Francis Rizzo died at Philadelphia on August 11th, at the age of fifty years. He was a native of Italy, and was graduated from the medical department of McGill University in 1877. For five years he resided in Florida, subsequently removing to Philadelphia.—Dr. John Rendell, of Brooklyn, was thrown from his surrey on Wednesday of last week, sustaining a fracture of the skull, and died in St. John's Hospital the following day, without having regained consciousness. He was a graduate of the Long Island College Hospital Medical School.—Dr. Theron Tuttle, of Brooklyn, died at his home in that city on September 16th. He was born in Hartford in 1833, and was a graduate of the College of Physicians and Surgeons, New York, in 1854. He had practised medicine in Brooklyn for nearly twenty-five years.

The Late Dr. John J. H. Love.—At a regular meeting of the Orange Mountain Medical Society, held September 10, 1897, the following resolutions were adopted:

"*Resolved*, That in the death of our late friend and associate, Dr. John J. H. Love, this society has sustained a loss which we deeply mourn. A constant attendant upon its meetings, its welfare was ever his earnest care. His voice was invariably raised in behalf of progressive medicine and surgery, and his well-weighed opinions were received with that attention and respect which they always merited.

"*Resolved*, That we tender to his family our sincere sympathy in their bereavement, and that a copy of these resolutions be spread upon the minutes of this society and published in the medical press.

"William Pierson, M.D.,
"H. B. Whitehorne, M.D.,
"James S. Brown, M.D.,
"Committee."

Society Reports.

TWELFTH INTERNATIONAL MEDICAL CONGRESS.

Held in Moscow, August 19, 20, 21, 22, 23, 24, 25 and 26, 1897.

Special Report for the Medical Record.

SECTION IN SURGERY.

(Continued from page 404.)

Fifth Day — Wednesday, August 25th.

Orthopædic Treatment of Tuberculous Joint Disease.—Dr. Dollinger, of Budapest, read a paper on this subject. He thought the important principle of the treatment of tuberculous joints with apparatus is as far as possible the absolute fixation of the joint with separation of the articular surface by gentle but firm extension. The apparatus must be as light and as unobtrusive as possible, and so arranged that the points of pressure will not interfere with nutrition of the skin.

Dr. Hoffa, of Würzburg, exhibited apparatus for practically treating all the affections of the lower extremities that may demand the help of the orthopædic surgeon. The principle worthy of attention was that the employment of flexible steel in the apparatus practically takes the surgeon out of the hands of the instrument maker. One of the great objections to the free employment of apparatus had been the state of servile dependence on the mechanic in which they placed the doctor. The fulfilment of special indications was often almost impossible, as the instrument maker would follow his models, but with this flexible steel the shape of the apparatus could be changed at will, and yet would be firm enough for all practical purposes.

Orrhotherapy of Cancer.—Dr. Sematzky, of St. Petersburg, presented a communication on the serum treatment of malignant neoplasms. Streptococcic serum was employed, but absolutely without results. Virulent cultures of streptococci were also employed; these seemed not only to do no good, but to be absolutely harmful. A thorough trial was given them, frequently several times in the same patient, though often against the speaker's better judgment, but no encouraging results could be obtained.

Dr. Pavlovsky, of Moscow, in discussing the subject, reported the case of a teacher in the public schools in whom a tumor developing on the jaw was diagnosed as sarcoma. It seemed inoperable from its size and from the probability of deep glandular involvement. Erysipelas toxins were used and with success, for the tumor had disappeared and for more than a year the man had been entirely well.

Dr. Fabrikant, of Kharkov, said that in his experience the serum treatment, as well as that by aniline injections, had given absolutely no results in cancer.

Permanganate of Potassium in Lupus.—Dr. Kachanovsky, of St. Petersburg, read a paper on this subject. He employs powdered permanganate of potassium. The powder, freshly prepared from dehydrated dried crystals, is applied in a layer, three to five millimetres in thickness, over the whole surface of the lupus and the suspected portions of the surrounding tissues. In case of deeper ulcerations with undermined edges, the powder is applied after curetting two or three times in order to level the uneven surface. In all cases a layer of medicated cotton is put over it to keep the powder in place and absorb the secretions and eliminated material. In most cases a single application of the powder suffices. He has employed the powder now in more than thirty cases since 1878, and always with complete success.

Hot-Air Treatment of Lupus.—Dr. E. Hollander, of Berlin, had first tried the local application of steam for lupus but without result, as the patients were unable to stand a temperature sufficiently high to affect the diseased tissues. Then he tried hot air. His apparatus consists of a Bunsen burner, on the top of which is mounted a coil with a tube passing through it. To one end of the tube is attached an air-pressure bulb for driving a current of air through the coil; the other end is left open. A current of air heated to 300° C. may be driven through the coil and directed very exactly by the patient himself, so that it affects only the diseased parts. The mode of action of the process is, according to the author, as follows: The intensely hot air produces an active contraction of the vessels of the skin and of the diseased tissues. They become blanched and bloodless; after two or three days the blood returns to the supporting framework of connective tissue, but not to the diseased granulation tissue. Cicatrization sets in and a radical cure results.

Dr. Schulz, of Duisburg, had had very good results from extirpation of the diseased part followed by Thiersch's skin transplantation. The success of the process depends on the thorough removal of the diseased tissue. If any of this is left, reinfection of the whole surface will often follow and absolutely prevent the skin grafts from taking.

Conservative Treatment of Hip Disease.—Dr. V. Menard, of Berck-sur-Mer, read a paper on this subject. From 1894 to 1897 he had had under treatment six hundred and fifteen cases of coxalgia. Two hundred and sixty-one of the cases were without the formation of pus. These were treated without question of operation, the lighter cases being kept at rest with continuous extension, the severer cases with absolute immobilization by plaster apparatus. During convalescence the patients were allowed to move around with an immobilization apparatus. In one hundred and eight cases an abscess had to be treated. All were treated with modifying injections of camphorized naphthol. In ninety-four cases a cure was obtained after from two to ten injections, very seldom more. In six cases a persistent fistula remained, and in eight cases in which after a long series of injections no improvement was noticed resection of the hip was done and was followed in seven cases by primary union, in the eighth by a fistula that persisted for five months. In the six hundred and fifteen cases of hip disease, in five years the mortality was twenty-two. There were nine deaths without operation, from meningitis, cachexia, and visceral tuberculosis; thirteen after operation, four of these from shock. The principle of treatment insisted on was not to convert a closed aseptic hip-joint abscess into an open one with all the dangers of mixed infection.

Intra-Articular Injection in Tuberculous Joint Disease.—Dr. Cazin read the paper in his own name and that of Dr. Duplay, of Paris. After having tried intra-articular injections of iodine for some time, the authors now limit themselves to the use of iodoform, either in the form of a mucilage or a ten-per-cent. ethereal solution. The solution in ether has the inconvenience of causing considerable pain, so they prefer the mucilage holding in suspension one and one-half grams of iodoform. The injections are made twice a week, unless improvement is slow, when they are made every second day. The results have been very satisfactory. It is especially in white swelling of the knee that the injections of iodoform have given good results when combined with immobilization, compression, and extension.

Massage in Surgery.—Professor Zabloudowsky, of Berlin, read a paper with the title, "Remarks on

the Employment of Massage in Surgery Supported by Observations from the Berlin University Surgical Clinic." He regarded massage as of the greatest use to the surgeon, and said that the method was so simple and its employment required so little time that all surgeons could practise it.

Flatfoot.—Dr. Bloch, of Paris, presented a communication on "The Treatment of Painful Flatfoot—Tarsoptosis and Tarsalgia—and the Cuboid Symptom." He said that there is a solidarity in the structures of the foot, and that the plantar arch like every other depends on the strength of each of its component parts. There is in the foot a *locus minoris resistentiæ*, and it is found in the cuneo-cuboidal convexity. Any muscular or ligamentary insufficiency uncompensated for makes itself felt at this joint and produces the so-called painful flatfoot. For this Dr. Bloch proposed the name tarsoptosis.

Suture of Arteries.—Dr. Djemil Pacha, of Constantinople, read a paper on this subject. He reported two cases of wounds of large arteries closed by sutures. In one of his cases, during an operation for mammary cancer, the axillary artery was torn, a slit fifteen millimetres long resulting. With a fine needle he sutured the arterial tear together, using five sutures. Then the connective-tissue coat was sutured above it. The arterial current was at once established, and only slight pressure for a few minutes was necessary to stop the exudation of blood at the points of suture. This was two and one-half years ago, and there is not the slightest trace of traumatic aneurism or any abnormality of the vessel. A second case of the same kind was treated in the same way, with like result.

Dr. Nitze, of Berlin, presented a communication on the same subject, and exhibited an instrument for the preservation of the arterial coats from undue pressure after suture. The divided halves of a cylinder of ivory or bone are fastened to the ends of a small pincette. When brought together around the artery they cover the sutured place and relieve the parts from pressure, so preventing the danger from secondary hemorrhage which might result from overtension on the sutures. He considers that it is no longer justifiable for a surgeon to tie a large artery and run the risk of gangrene. Even when an artery is torn completely across its lumen may be restored after resection and suture.

Metastases of Endotheliomata.—Dr. Scriba, of Tokio, read a paper "On the Clinical Diagnosis of Endotheliomata and their Special Manner of Giving Metastases." He said that these tumors, arising from the endothelium of the smallest vessels, are much more frequent all over the body than is generally supposed. They have been taken for carcinomata most frequently, from their tendency to metastasis in the lymph glands, but sometimes also for sarcomata. Clinically they may be differentiated by their metastases differing from sarcomata, in that they give metastases to the lymph glands, and from cancer because their metastases are not so hard, grow more rapidly, and are not painful.

Spontaneous Gangrene.—Dr. I. Munk reported a case of spontaneous gangrene of the fingers, occurring in a child, three years old, within a short time after a severe attack of scarlet fever. He thought it very probable that spontaneous gangrene in run-down subjects is due to the fact that the lowered resistance of the tissues enables microbes in the blood current to make an extremely rapid growth when the blood current is slow in the extremities, with the resulting production of an amount of toxin that acts fulminantly in the local tissues, causing their death.

Roentgen Rays in Diagnosis.—Dr. Levy, of Berlin, read a paper on a new development in the application of the *x*-rays for diagnostic purposes. The new method avoids all the disadvantages of inflammation of the skin, long exposure, etc. Its success is based upon: (1) A special form of tubes, which gives double and triple the usual quantity of *x*-rays; (2) by using a special "shortening" fluorescent screen; and (3) by employing special plates or films which are coated with the sensitive material on both sides. By means of this apparatus it is possible to take a radiograph of any part of the human body, even the pelvis, in a time not exceeding one minute.

Excision and Suture of the Ulnar Nerve, Six Months after Accidental Division.—Dr. G. B. Ferguson, of Cheltenham, England, reported the case of a young lady who fell through a skylight and cut herself seriously, including the right ulnar nerve. This was not noticed at first, and the wounds were sewn up. Very soon, however, muscular weakness was noticed in the healed arm and total ulnar anæsthesia. An operation for suture was proposed and declined, and every alternative plan of rubbing and electricity was employed. At the end of six months the arm was much shrunken and of but slight use, and the hand was quite claw-like, owing to the shrivelling of the interossei. Owing to the anæsthesia the affected side of the hand was constantly receiving unperceived injuries, and on one occasion she literally boiled her little finger to warm it. This was, of course, followed by long and painful sores. At last, after six months, the parents asked for an operation. The divided ends were soon found, much separated and much degenerated. Fully an inch was excised, which made it hard to bring the ends together. But after considerable separation and stretching this was effected, and a splice was made with catgut. After two days sensation began to return and the parts soon became even hyperæsthetic. It was many months before the plumpness of the muscles began to return, but return it did, and now, rather more than two years after the operation, all is strong and normal, save that that hand is wont to be colder on the ulnar side.

Skin Grafting.—Dr. Linngrenn, of Trelleborg, Sweden, read a paper "On the Faculty of the Human Epithelium to Preserve its Vitality apart from the Organism for Purposes Especially of Skin Transplantation." He has in a large number of cases transplanted to the surface of fresh and granulating wounds portions of human epidermis, after they had been kept for from one day to six months in sterile serum. In most of the cases the grafts took and formed a layer of skin just as in the ordinary method of skin transplantation.

Irrigation Treatment of Gonorrhœa.—Dr. Vigneron, of Marseilles, read a paper on the results of the irrigation treatment with permanganate of potassium in eighty-three cases of urethritis in which gonococci could be demonstrated. In twenty-three cases treatment was begun within forty-eight hours after the appearance of the discharge. These gave the most favorable results, viz., eighteen cures after from four to fourteen irrigations; four cures after from six to eight weeks of treatment; one case disappeared from observation after the ninth irrigation, still having some discharge but without gonococci. All the others were perfectly well fifteen days after their last treatment. All the twenty-three cases except three were cured by the permanganate. These had to have two or four irrigations with sublimate to complete the cure.

Pathogenesis of Deformities.—Dr. C. Ghillini, of Bologna, read a paper on this subject. He held that all deformities of bones are due to pathological conditions in the epiphyseal cartilages. This is true not only for deformities that occur in the articular ends of the bones and in the immediate neighborhood of the epiphyses, but also in deformities occurring in the diaphyses of long bones. It is true that here ab-

normal tension, pressure, and traction play a rôle in producing deformity, but they act by affecting primarily the epiphyseal cartilage.

Incision of the Pericardium.—Dr. Voïntch Sinogensky, of St. Petersburg, read a paper on "The Removal of Moderately Large Purulent Exudate in the Pericardial Sac by Open Incision." He said that, while a number of methods may be employed to remove the purulent exudate from within the pericardium when it is of considerable size, most of these methods are not so applicable to small quantities of exudate. The weightiest consideration in the matter is the position of the anterior edges of the pleura as regards the anterior thoracic wall. The space between the pleura in front is not very uniform in size and position. Small amounts, not more than one hundred and fifty cubic centimetres of purulent pericardial exudate, do not alter the position of the heart and pericardium as he has noted in thirteen cases on the cadaver, but a number of different diseases of the internal organs materially change the position of all the thoracic viscera. In general it may be said that there is more room for a longitudinal than for a transverse incision. Despite the various positions possible to the pleura in front, there are certain points that act as guides. An incision made between the fifth and seventh costo-sternal articulations avoids the pleura and pericardium. An exploratory puncture made in this line with a fine needle which is inserted only moderately deep, 1.5 to 2.5 cm., is absolutely without danger. The tubercle of the sixth left sterno-costal articulation serves best as a guide for the skin incision and is usually easy to find on the surface.

SECTION IN MEDICINE.

Third Day—Monday, August 23d.

Clinical Forms of Hepatic Cirrhosis.—Dr. Chanfard, of Paris, read a paper with this title. The clinical analysis of the different types of hepatic cirrhosis, to be complete, should show in each individual case the anatomical process, the pathogeny, and the course. First he defined what was to be understood by the term cirrhosis of the liver. Three conditions must be present in order to justify the diagnosis of cirrhosis: (1) The proliferation should be general, distributed throughout the entire liver; it may predominate in one or another region, but it must always be diffuse. A pericystic or pericalculous sclerosis cannot be called cirrhosis. (2) The new-formed connective tissue must be fibrous and full grown, rich in elastic fibres approaching that of cicatricial tissue. (3) The process must not be absolutely confined to the interstitial elements, but the cells must also be affected. To classify properly the hepatic cirrhoses one must take into consideration the anatomical changes and the nature of the agent producing them; in other words, the classification ought to be anatomical and at the same time etiological. We cannot understand why some hepatic cirrhoses run an acute, others a subacute, and still others a chronic course, unless we appreciate that we are in the presence of a process more or less distinctive, according to the manner and the duration of its action. Clinically, as well as by experimental pathology, we know that every toxic agent or infection capable of producing a cirrhosis can, under proper conditions, provoke any degree of inflammatory or degenerative reaction in the hepatic cell. We learn this by the study of the principal forms of cirrhosis, where we see that the irritant action of large doses of a given agent kill the cell, while the same agent in small doses continued over a long period provokes sclerosis and only later or secondarily affects the cell. So the irritant agent may be too powerful or too feeble to produce cirrhosis, as we see in the case of phosphorus or lead poisoning. Again, under proper conditions the one agent may act only on the cell or it may act to produce cirrhosis; thus the toxin of syphilis in the second stage may cause a syphilitic icterus, while at another period, when less virulent, it is essentially cirrhogenic. Tuberculosis shows this even better. If we inoculate the liver experimentally with human tuberculosis, it causes not only tuberculosis but fatty and coagulation necrosis in the liver; if we inoculate it with aviary tuberculosis, sclerosis is the usual result. Cirrhosis is therefore always the result of the action of a poison in small doses long continued; the sclerotic reaction of the connective tissue corresponds to a defensive resistance on the part of the liver to the poison, and when the toxic agent is too violent it provokes necrobiotic degeneration, but not cirrhosis. All this applies to venous cirrhosis. As to biliary cirrhosis, the question is much more obscure, since we know nothing certain of its pathogeny. If it is infectious in origin, as affirmed by Hanot, it would appear to depend on a prolonged bacillary infection, and so comes under the laws just demonstrated. A cirrhosis once begun becomes soon a definite disease with its symptoms, its complications, its evolution, and its termination. These different clinical elements so group themselves as to individualize a series of types of cirrhosis, of which the descriptions are classic. But one has a very incomplete idea unless he takes into consideration also the anatomical and functional condition of the hepatic cells. Hanot expresses this very aptly when he says that the diagnosis of cirrhosis is made from the condition of the connective tissue, the prognosis from the condition of the hepatic cells. From experiments on animals (the removing of portions of the liver) we know that histologically hepatic lobules hypertrophy, that they can double or triple their size, at the same time that new lobules are appearing and developing alongside them; so we can believe that compensatory hypertrophy is a general law. Acknowledging this, we may distinguish three groups of facts: (1) The compensatory hypertrophy is insufficient or masked by the destruction more or less rapid of the glandular elements. Such is the case in the atrophic cirrhosis of Lænnec. (2) The compensatory hypertrophy may be sufficient to allow the patient years of life, but not a cure. The sclerotic process continues its work till one day secondary icterus appears and the patient dies. It is thus that the hypertrophic biliary cirrhosis of Hanot kills. We know how long the course of this disease is, and if the patient dies of an intercurrent affection we find the hepatic cells healthy, hypertrophied, or in full karyokinetic activity. But if the cirrhosis has time to complete itself we find the trabeculæ parted, the hepatic cells fragmented, deprived of their nuclei, or even fatty granular, and this especially in the centre of the lobules. (3) Finally the compensation may remain sufficient for such a long time that an apparent cure has taken place. We see this in the hypertrophic alcoholic cirrhosis of Gilbert and Hanot. From the works of these authors we know how different is the prognosis when the liver is atrophied or hypertrophied. In the latter case it is not rare to see under milk diet and diuretic medication the ascites disappear and the general condition improve to the point of apparently perfect health. The patient seems actually to be cured. The conclusion therefore is, the author said, that the liver reacts under the form of cirrhosis only when the pathogenic agent is relatively moderate and is prolonged; that the sclerotic process is to a certain point a proccess of protection and defence to the hepatic cell; that this in its turn participates in the disease either by compensatory hypertrophy or following the conditions is destroyed.

Dr. Gilbert, of Paris, followed with a communication on the same subject. He distinguished two grand categories, after Hanot: simple cirrhosis and complicated cirrhosis. In the latter, by addition to the sclerosis and atrophy or hypertrophy of the hepatic cells, there were various degenerations always extending to the parenchymatous element. In simple cirrhosis the pathogenic agent may come from within or from without the organism. The cirrhoses of auto-intoxication are the dyspeptic, the gouty, and the diabetic.

In dyspeptic cirrhosis Boix described the liver as large, smooth, remarkably hard, without increase in volume of the spleen, without icterus, ascites, or collateral venous ciculation. The duration is very long, even ten years. As a cause of this we may suspect the action of acetic acid, which is so frequently formed in the stomach of dyspeptics. Among the poisons from without which cause cirrhosis, the speaker mentioned lead and alcohol. It is more than a disputed question, he said, whether the former can cause cirrhosis; the latter causes it under two forms, viz., atrophic (Laennec) and hypertrophic (Hanot and Gilbert). Under the head of infectious cirrhosis, he mentioned those caused by the eruptive fevers, by typhoid fever, cholera, syphilis, and tuberculosis. Under the head of cirrhosis by auto-infection we have the biliary cirrhosis of Hanot and biliary cirrhosis by obstruction. Mechanical cirrhosis is another name for cardiac cirrhosis. The complicated forms of cirrhosis are those accompanied by fatty, amyloid, or pigmentary degeneration, necrobiosis, diffuse or nodular hyperplasia, and adeno-epitheliomatous changes.

Intercellular Hepatitis.—Dr. Carmona y Valle, of Mexico, described a special form of hepatic cirrhosis, occurring in the city of Mexico, which, he said, is not spoken of in the text-books. It is characterized by an enlargement with induration; constant icterus; continued, remittent, or intermittent fever; hemorrhage; digestive disturbances with continuous bilious diarrhœa; cerebral disturbances with ataxo-adynamic phenomena; frequently ascites; and it finally terminates in death. Its mean duration is six or eight months; but it may kill in much less time, or may last as long as a year and a half. It differs from the hypertrophic biliary cirrhosis of Hanot by its much more rapid progress, by its almost continuous fever, by the frequency of ascites, and by the fact that the spleen does not hypertrophy. The proliferation begins in the intra-hepatic veins, extends rapidly to the trabeculæ of the lobules and afterward to the ramifications of the portal vein. There is always destruction of the cells, and in some cases the connective-tissue proliferation is so abundant that it obstructs the vessels, so causing nodules, more or less large, of necrobiotic tissue which softens and forms cavities full of a creamy fluid.

Orrhodiagnosis of Typhoid Fever.—Dr. Widal, of Paris, read a paper on the serum diagnosis of typhoid fever, in which he gave in detail his method of obtaining the reaction and offered a theoretical explanation of its production.

Dr. A. Mills, of Brussels, followed with a paper entitled "On the Gruber-Widal-Grünbaum Sero-Diagnostic Method of Typhoid-Fever Auto-Reactions." In twenty-eight serum reactions made with cultures of like ages, but of variable virulence, the speaker said, he had constantly found that the rapidity with which agglutination was produced was inverse to the power of the virulence of the typhoid bacillus. He thought therefore that it was necessary to mention three elements before giving the results of a serum reaction. These are (1) the dilution of the serum of the patient, (2) the duration before the appearance of the serum reaction, and (3) the virulence of the culture employed. Dr. Mills then spoke of auto-reactions. It was interesting, he said, to determine whether the action of the blood in typhoid fever was the same when placed in the presence of other bacteria as when made to react through its own infecting bacteria. Out of eight cases the hetero-serum reaction was six times produced more quickly than the auto-serum reaction. In two cases the contrary took place. These differences were in perfect accord with the state of virulence of the cultures. In discussing the question as to whether the serum reaction is due to a natural or to an acquired immunity, he said that it could not be a natural immunity, because he had always observed that the agglutinative power increases with the infection so long as the intoxication of the blood is not too considerable, and that it does not disappear immediately with the infection. Consequently it must be an acquired immunity.

Dr. Widal, of Paris, asked Dr. Mills how he came to associate three names in this reaction, when up till now it has always gone under one name.

Dr. Mills answered that Gruber was the first to point out certain points in regard to this agglutinative reaction, and after Widal Grünbaum had suggested certain modifications.

Dr. Widal said that personally he esteemed both the gentlemen mentioned, admired the work that they had done, and felt it an honor to be associated with them, but till now he had not known that Grünbaum had modified the reaction to any such extent that would justify the addition of his name, and Gruber did not apply the reaction to the diagnosis of the disease. The principal point, however, was that he did not think Mills had the right to call the reaction by names not before associated without the permission of the men in question. As Mills had not asked his (Widal's) permission, he requested that his name be withdrawn from the title of the paper, and if it was lawful for the president to make the change he desired him to do so.

The President said that under the circumstances the three names would be erased from the title.

Orrhodiagnosis, Orrhoprognosis, and Orrhotherapy of Relapsing Fever.—Dr. Loewenthal, of Moscow, read a paper with this title.

Orrhodiagnosis: The foundation of this method consists in the influence of the specific bactericidal properties of the blood during each apyrexia of relapsing fever. The author had had thirty cases with a positive result, as shown by the course of the disease; nine cases of other acute infectious diseases, with negative result; and fourteen cases verifying the specificity of the blood during the apyrexia. From a study of these experiments he had come to the following conclusions: (1) The serum diagnosis furnishes us with a positive method for diagnosticating the disease in the course of one or two hours, when the patient is first seen in the apyretic period. (2) This is true even in abortive attacks (third and fourth attacks, or slight paroxysms) when the blood contains but very few spirilla. (3) After inoculating the patient with the anti-spirillum serum there will be no relapse in half of the cases. (4) The stay in the hospital will be shorter for the patient, especially since by error such cases are now often diagnosed as simple malarial fever.

Orrhoprognosis: The procedure is the same as in that of serum diagnosis. This method gives an exact criterion by which to prognosticate the cause of the disease. Acccording to Dr. Loewenthal's researches (fifty-eight cases), when the duration of the reaction was for one hour seven days after the first apyrexia, a relapse never followed.

Orrhotherapy: The speaker had inoculated eighty-four patients at the beginning of the first apyrexia—fifty-three per cent. relapsed, forty-six per cent. ended after one attack. During the same time, of one hundred

and fifty-two cases not treated by the serum, in only sixteen per cent. did the disease end with one attack.

Dr. Metchnikov suggested that the explanation of the spirillicidal action of the blood during the apyretic period of recurrent fever was not so simple as Dr. Loewenthal would seem to regard it. The whole reaction would seem to prove that there is some other influence at work besides spirillicidal material freely circulating in the blood. Gabrichevsky has shown that no definite rule can be laid down as to the spirillicidal power of the apyretic blood. Sometimes it kills in one and one-half hours, sometimes only in eighteen, sometimes not for thirty-six hours. Normal human blood will do the same thing in eighteen to twenty hours as a rule. In experiments on apes Bardach has shown that during the crisis of the fever and in convalescence living spirilla appear in the spleen and are infective when inoculated into other apes. If the liquid obtained from the spleen be gently heated it loses its infective property, thus showing that it is not in the form of spores that the organisms are present. It is almost proven then that it is not a new generation of organisms with greater virulence that causes the second attack after the apyrexia, but that some influence holding the organisms in check has been removed or paralyzed in its action. This is not likely to be any substance circulating freely in the serum, but is much more probably some living influence that in its cycle of existence loses its resistant power. This would speak very strongly for the phagocytic action of the leucocytes in relapsing fever. The irritation in the blood-making organs during an attack causes a leucocytosis which sets free a number of phagocytes to englobe the spirilla and hamper their action: after a while this generation dies off, setting free the spirilla that have not been killed and so leading to another attack.

The Pathogenesis of Typhoid Fever.—Dr. Francules, of Roumania, read a paper entitled "The Pathogenesis of Typhoid Fever and the Errors of the Current Microbian Theory," of which the following is a *résumé*: (1) Typhoid fever may, under certain conditions, arise spontaneously, that is, without the presence of the bacillus of Eberth. (2) The bacillus coli communis may, under favorable conditions, acquire pathogenic properties and produce typhoid fever. (3) It can preserve and transmit these new qualities to future generations. (4) These new generations may adapt themselves to new conditions, and, obeying the law of atavism, return to their primitive state. (5) It is incorrect to say that a germ must always and everywhere preserve its form and specificity, especially an absolute specificity.

The Malarial Parasite of Tertian Fever (with Demonstration by Lantern Slides).—Dr. Judson Daland, of Philadelphia, read the paper. The photographs from which these lantern slides were made were secured in the following manner: The thumb was cleansed first with water, then with alcohol, and finally with ether. It was then punctured: the emerging droplet of blood was placed upon a slide and then upon a warm stage and photographed within from twenty to forty minutes. The initial magnification was from one thousand to two thousand diameters, and a Zeiss apochromatic oil-immersion lens was employed. Not infrequently three photographs of the same parasite were taken at intervals of three or five minutes. The first picture, from a case of tertian fever, showed a large and small matured extracorpuscular malarial parasite, the pigment showing very well but not sharply outlined, as these particles were in a rapid dancing-movement at the time the photograph was made. The second picture showed a large moderately matured intracorpuscular plasmodium. The red blood corpuscle acting as the host of the parasite was a macrocyte. The original attack of the tertian malaria four years ago was acquired in India, since which time the disease recurred each succeeding autumn. This patient had received several hypodermatic injections of the bimuriate of quinine and urea with but little benefit. The third picture showed a matured extracorpuscular body photographed thirty minutes after removal from the patient during the interparoxysmal period. The duration of the exposure was one second and the magnification two thousand diameters. A second photograph was made in four minutes and no change was observed. A third photograph was made in six minutes, when the body was seen in the act of disintegrating. The large masses of pigment were seen free in the plasma and the protoplasm that had formed the parasite was seen as a number of globules of various sizes. This observation was especially interesting as showing the last step in the life history of a matured extracorpuscular malarial body. The sixth picture showed a free malarial body; the pigment granules were quite large and when photographed were in lively motion. The blood was taken from a case of tertian intermittent fever at the beginning of a chill. The seventh picture showed the same parasite ten minutes later, during which interval the pigment had shown a tendency to a bipolar distribution with a clear space in the central region. The eighth picture showed the same parasite ten minutes later, when the beginning of an hour-glass contraction may be plainly seen. The ninth picture showed the same parasite forty minutes later, when the body had completed its division. It would seem from the series that one of the methods of the multiplication of the plasmodium is by division. The last picture showed beautifully a crescentic body. Plainly could be seen what appeared to be the shell of the red corpuscle in which the parasite was inclosed. The pigment was motionless. The case was one of quotidian fever and the photograph was taken upon the third day of the absence of fever, during which time the patient received sixty grains of quinine in divided doses. Five days later, or eight days after the last paroxysm, these crescentic bodies were still to be seen, although but few in number. It seems not improbable that these crescents represent certain of the parasites that have come under the influene of the quinine and have been arrested in their development.

Gastroscopy.—Dr. Revidzov, of Moscow, read a paper on the technique of gastroscopy. The author proposed the following modification in order to replace the direct introduction of the metallic tube, which is sometimes dangerous: An English œsophageal sound, almost equal in size to the exterior metallic tube of Rosenheim's gastroscope, is introduced while the patient is in the sitting posture. Then, with the head bent backward, the othe. two tubes of Rosenheim's gastroscope are introduced—a procedure which can usually be done without difficulty.

Surgery of the Lung, like that of the viscera, has of late made much progress, thanks to the perfection of our anatomical knowledge and to the improvement in operative procedures for the arrest of hemorrhage. Equally favorable conditions for surgical intervention do not occur in all affections of the lungs. Wounds caused by contusing bodies, by stabbing and cutting instruments, and by gunshot projectiles of small and medium calibre, usually heal well without causing suppuration or troublesome reaction. The danger which results from such injuries is due, not to the injury of the lung structure itself, but rather to the multiplicity and extent of the wounds and to the lesions of important neighboring parts. The surgeon should not intervene too hastily in these injuries.—Péan.

SECTION IN SURGERY.

(Concluded from page 457.)

Third Day—Friday, September 3d.

Resection of the Intestine.—Dr. F. J. Shepherd, of Montreal, reported a case of successful removal of six and one-half feet of intestine. The patient was a man, twenty-eight years old, who had noticed for some months an enlargement of the abdomen. The diagnosis was a retroperitoneal lipoma. On opening the abdomen, the tumor was found adherent anteriorly and laterally. It grew from the mesentery. Three feet of ileum attached to the growth, as well as nearly two feet on either side, had to be removed.

Penetrating Wounds of the Abdomen.—Dr. Tobias Nuñez, of Mexico City, presented a paper on "The Diagnosis and Treatment of Penetrating Wounds of the Abdominal Cavity." He pointed out how difficult it was to ascertain the true extent of wounds of this sort and the amount of damage done. The two great dangers were peritonitis and internal hemorrhage, the symptoms of which were well known. These complications might occur separately or together. If it was clear that the intestine was wounded, laparotomy was called for. But, generally, if the indications did not call for radical measures, the speaker leaned to conservatism in treatment.

Surgery of the Bile Ducts.—Dr. A. H. Ferguson, of Chicago, read a paper on this subject. He said that the surgeon alone could treat these cases successfully. Stone in the gall bladder or any of the bile ducts was as clearly a case for the surgeon as stone in the bladder. He did not mean that operation should always be performed as soon as a diagnosis was made, but a surgeon should be at hand to sit in judgment upon the clinical evidence. The speaker reported forty-six cases of various affections in this region which had come under his care.

Intestinal Obstruction.—Dr. A. B. Atherton, of Fredericton, New Brunswick, reported a case of intestinal obstruction caused by strangulation of a loop of ileum by Meckel's diverticulum. The patient, a man with a small umbilical hernia, had suffered from attacks of cramps once or twice yearly, attended latterly by vomiting and looseness of the bowels, induced apparently by errors in diet. After a dose of calomel these symptoms were relieved until the last attack, when this did not produce movement of the bowels. Vomiting was persistent, and when the man was seen by the speaker in consultation the facial expression was bad. The temperature was 99° F. The belly was distended. Tympanites was marked in the umbilical region. Tenderness and pain were especially marked below and to the right of the navel. There was no induration. Meckel's diverticulum was of the size and shape of a pear and partly gangrenous. A good deal of force was needed to draw the diverticulum out. The patient rallied fairly well, but his pulse ran up to 150, temperature to 101° F. within twenty-four hours, and the face looked pinched. The temperature afterward fell to normal, but the pulse remained high and the patient became delirious, and died thirty hours after the operation. Autopsy showed a loop of ileum protruding through a hole in the mesentery. There was considerable intestinal distention in the neighborhood, but no peritonitis. Only one case like this, so far as the speaker knew, had been reported.

Ureteral Stones.—Dr. Jordan Lloyd, of Birmingham, presented a communication on stone in the ureter and its treatment. He was struck some ten years ago, when work in renal surgery began, by the number of failures in discovering renal calculi. It happened in the hands of many men that in patients who presented all the symptoms of renal calculi none was found. Some had gone so far as to remove the kidney, and then had found no stone. In some of these cases the speaker was sure the condition was one of stone in the ureter. He reported the case of a man who had suffered from typical symptoms of renal calculus for three and a half years. An operation was performed, but no stone was found. Forty-five days later the patient was seized with acute pain which lasted a few seconds and then disappeared. In five or six hours a calculus was passed. In his next patient suffering in this way he resorted to the expedient, which he considered of great importance, of giving the patient a sudden very strong blow over the suspected site of the stone. This hurts only for a moment, causing a stabbing pain, very characteristic of stone. This patient, besides paroxysmal nephralgia, had shooting pains about the lower abdomen and hips. Hæmaturia was present. There was absence of kidney tenderness. His first step in diagnosis was to examine the bladder to determine that there was no stone there. The urine should be examined microscopically for blood. Then a group of symptoms should be looked for which are always associated with what he called "water-logged kidney," a "urotoxæmia." The patient looks excessively ill. The skin is moist, the pulse rapid (160 to 180), and the temperature is subnormal. There is abdominal distention caused by paresis of the intestines and the distress is extreme. He had been called in consultation to see a man by his physician, who stated that a curious condition was present—that the heart and lungs seemed to be much crowded upward, and he was unable to tell why. The man on inquiry gave a history of stone, and had left lumbar colic. This gave a clew. The ureter had become impacted and water-logged kidney was present, as indicated by one of its typical signs, viz., intestinal distention, which accounted for the crowding up of the thoracic viscera. Aspiration was done to relieve the distention. At the autopsy the pelvis of the kidney and the ureter were much dilated. Lumbar nephralgia with localized tenderness pointed to the position of the stone. Most cases of impacted stone would be found within the lower three inches of the ureter. The treatment in these cases was to cut for the stone, the sooner the better. If it was located near the bladder a suprapubic cystotomy gave the best results. The bladder should be opened, the ureter split up, and the stone extracted.

Dr. W. W. Keen reported a case in which there were symptoms of appendicitis. The fever was slight; the pain centred around the umbilicus, later being felt in the iliac fossa. There was nothing suggesting ureteral or renal trouble. On opening the abdomen no appendix was found. He did not think of stone in the ureter until the next day, when he did so with a strong twinge of conscience. Ten months later he removed a calculus from the patient's bladder. Dr. Keen said he thought that in every case of renal colic in which within two or three days no stone is passed the bladder should be evacuated with a Bigelow evacuator.

Appendicitis and Pyosalpinx.—Dr. Lapthorne Smith, of Montreal, gave a brief account of seven cases of appendicitis complicating pus tubes. He explained a new method of dealing with the appendix. Instead of leaving a stump and searing with carbolic acid, which he said was frequently followed by fistulæ by reason of the mucous surfaces not uniting, he cuts the appendix off flush with the bowel, thus practically treating a hole in the bowel.

Dr. Marcy, of Boston, said that he united the muscular and mucous coats and then invaginated the stump so as to bring the peritoneal coats together.

SECTION IN MEDICINE

Second Day—Thursday, September 23.

Crossed Hemiplegia.—Dr. J. E. Graham, of Toronto, reported a case of crossed hemiplegia, the result of injury of the pons Varolii, which came under his observation five years ago. The history taken at that time was as follows: A. L——, aged ten years, was perfectly well. When eighteen months old, fell, while playing, and a slender jagged end of a spruce stick, about two feet long, entered the mouth and penetrated the soft palate. In the fall, the stick broke off at the line of the teeth and was so firmly embedded in the tissue that it had to be moved from side to side and much force used before it could be drawn out. The sliver measured between three and four inches. Profuse hemorrhage followed. The accident occurred at 5 P.M. and the patient cried until 11 P.M., when vomiting of clotted blood commenced and immediately after vomiting convulsions set in which lasted two hours. A second series of convulsions similar to the first, but shorter in duration, came on the next day. On the third night he had a third convulsive attack and during the afternoon a fourth. The latter was followed by pain, which continued till morning, when paralysis of the right arm and right leg was noticed with affection of the left side of the face. The left eye was turned slightly inward and the pupil was contracted. He swallowed liquids with difficulty. No solid food was given. He vomited occasionally for two weeks and remained in bed for seven months. Since the recovery of his strength, he had had convulsions, at first several in a day, but latterly less frequent. The series would often last seven or eight hours. Latterly they have been only ten or fifteen minutes and sometimes five minutes in duration. For the last five years they have occurred at night and are more frequent during the fall of each year. Constipation seems to bring on the convulsions. His mind is always clear, but he is not so bright as other boys. The affected side is always colder than the other and the right hand, which is rigid during the day, becomes flaccid at night. On examination in 1892 the right chest was one and three-quarters inches smaller than the left, while the circumference of the right arm, forearm, thigh, and leg averaged about one inch less than the corresponding parts of the left side. The face was drawn slightly to the left. No motion of the muscles of the right forearm was possible except slight additional flexion of the fingers, which were always considerably flexed and could not be extended by ordinary force. Motion of all the muscles of the humeral region could be made with some awkwardness. In the lower extremity all the muscles seemed capable of motion, but the foot was capable of only about half the normal flexion on the leg. The patient had an awkward limp which seemed due in part to the loss of motion in the ankle-joint and in part to lessened general power over the muscles of the joint. The patellar reflex was less on the right than on the left side. Ankle clonus was absent, also the cremasteric reflex. The condition present now differs very little from that of five years ago, except that now there is no squint. No similar case, as far as the speaker knew, had been reported.

Dr. Mackenzie, of London, said that the fact that the paralysis did not develop for three days showed that it was due to an inflammatory condition.

Dr. Angell, of Rochester, spoke of a case of tumor of the pons he had had, which gave similar symptoms and which showed no reaction of degeneration in the muscles. He considered the paralysis in Dr. Graham's case therefore due to hemorrhage outside of the pons and not in it, otherwise the muscles would have shown reaction of degeneration.

Bacteriology of Pertussis.—Dr. Koplik, of New York, read a paper on this subject. The small white pellets found in the sputa when examined show a very small bacillus. In sixteen cases examined the bacillus was found in thirteen. It is motile, grows on agar, gelatin, blood serum, not on potato. It is one-half or one-third the length of the diphtheria bacillus, and is an exceedingly delicate organism.

Cardiac Murmurs.—Dr. Musser, of Philadelphia, read a paper on the murmurs of heart disease. Organic murmurs often disappear on change of position of the patient, but only rarely is there a disappearance of the mitral murmur due to organic disease. Often cases in which murmurs are present for a long time before death show no evidences at the autopsy of disease of the valves. The order of disappearance of organic murmurs is: (1) mitral obstruction, (2) aortic regurgitation, and (3) mitral regurgitation.

Tuberculin.—Dr. Whitaker, of Cincinnati, reported his six years' experience in the use of tuberculin. He mentioned the various theoretical objections to its use, but said that in no case during the past six years had any bad effects had been observed, nothing other than the characteristic reaction. It was without doubt a most valuable means of diagnosis. As soon as tolerance of the treatment has been effected it should be stopped and later commenced again. In nearly all cases there was improvement at the first, but as the fever in late cases was due to the products of other micro-organisms, streptococcus, etc., tuberculin would not be of much service here. Many times cases showed very great improvement, and although it could not be said that this was due to tuberculin entirely it certainly had a beneficial effect. Tuberculin was contraindicated only in miliary tuberculosis.

Arthritis Deformans.—Dr. James Stewart, of Montreal, opened the discussion on arthritis deformans, especially its relation to rheumatism, nervous diseases, and tuberculosis. He based his remarks on the observation of forty cases which he had had in Montreal; of these twenty were in males and twenty in females. This proportion varies from the usual figures of five males to one female. There was a family history of some form of rheumatic affection in eight cases, of tuberculosis in five, and of a neuropathic tendency in four cases. As to exciting causes the following were noted: There was a history of gonorrhœa in thirty per cent. of the male cases, and in three of the male cases was a history of two or more attacks. In the female patients, however, there was, with the exception of one case, an entire absence of symptoms pointing to a past genito-urinary disturbance. For a long time it had been thought that there was an intimate relation between uterine disease and rheumatic arthritis. Next to gonorrhœa, exposure to cold was considered the most likely exciting cause. It appeared to be the sole or chief cause in five of the forty cases. The next most frequent cause was worry, which was present in four cases. Three patients had had subcutaneous abscesses, two double otitis media, two influenza, and two tonsillitis. Typhoid fever, pertussis, and diphtheria were each considered the chief cause in one case. In fifteen per cent. no cause could be ascertained. More than fifty per cent. of the cases had thus some previous infective trouble, the most frequent being gonorrhœa. The reasons usually advanced for adopting the nervous origin of rheumatoid arthritis are: (1) The fact that in certain diseases of the spinal cord, as tabes, syringomyelia, progressive muscular atrophy, joint changes of a somewhat similar character are met with. (2) The very frequent early and pronounced muscular atrophy observed in cases of rheumatoid arthritis. (3) The history frequently obtained of causes

which have a marked affect in lowering the resisting-power of the central nervous system to disease. (4) The frequent onset of rheumatoid arthritis with symptoms of a nervous character, symptoms pointing to a central or peripheral nerve disturbance. In ten of the forty cases tingling and numbness of the extremities preceded the attack. It is difficult to explain the marked and early atrophy of muscles that occurs in rheumatoid arthritis. No matter what the cause is, it must be due in the first place to some change in the joint and not to any supposed changes in the spinal cord. It is in the first place an arthritic affection. The speaker had never been able to ascertain that there was an objective disturbance of sensation in rheumatoid arthritis. There was never a loss of sensation. Of the series of forty reported cases in only three was there a history of tuberculous trouble, a proportion not greater than if as great as in people in good health. Indirectly a tuberculous tendency may, by lowering the resistance, tend to bring about rheumatoid arthritis, and it is only in this sense that there is a connection between the two diseases. In a very considerable proportion of all cases a history of rheumatism is forthcoming. In four of the forty cases there was a very clear history of acute rheumatism. In at least thirty per cent. the onset was that of either acute or subacute rheumatism—the unavoidable inference being that a very intimate connection exists between rheumatoid arthritis and acute and subacute rheumatism. There is no recognized well-marked dividing line between chronic rheumatism and rheumatoid arthritis. In Germany and France it is the custom to call cases chronic rheumatism which in England would be called rheumatoid arthritis. As yet we have no absolute proof of rheumatoid arthritis being due to a micro-organism, but it is highly probable that it is. In the speaker's opinion the most valuable of all methods of treatment is the use of baths of superheated dry air. Generally a considerable increase in the mobility follows the use of a few baths.

Dr. Hingston Smith, of Bristol, said that the disease was a chronic polyarthritis and not rheumatism. The fact that thirty per cent. of male cases had had gonorrhœa speaks strongly in favor of microbic origin. It is perfectly clear that the wasting of the muscles is due to non-use. The carbonate of guaiacol is said to have been useful in early cases.

Dr. Lindsay, of Belfast, thought there was no justification of a relationship between rheumatoid arthritis and tuberculosis; but the nervous theory could not be disposed of so summarily, on account of the presence of acute atrophy. He had seen many cases develop after chronic rheumatism.

Dr. Jacobi, of New York, said that in acute articular rheumatism we have to do with an affection of the synovial membranes, while in rheumatoid arthritis the cartilages are the parts affected.

Dr. J. C. Wilson, of Philadelphia, said the term rheumatism should be confined to the acute articular trouble. In rheumatoid arthritis there is a development in the early stages of successive attacks similar to light attacks of rheumatic fever.

Dr. T. D. Griffith, of Swansea, regarded the condition as a symptom similar to eczema, and not a specific disease like gout or small-pox.

Dr. Gibney, of New York, advised the use of hot air and of an appliance regulating the amount of motion of the joints; absolute rest was necessary in the early stages.

Dr. Tyson, of Philadelphia, used general tonic treatment, arsenic, etc.

Atony of the Rectum.—Dr. George Acheson, of Galt, read a paper on this subject. In the treatment of these cases it is of the first importance to discover and remove, if possible, the cause, such as any displacement of the uterus, a pelvic tumor, etc. Much may be accomplished by a hygienic mode of living: regular habits; attention to diet; using more of the coarser foods, vegetables, fruits, and fats; exercise in the open air; cold bathing; massage; drinking plenty of water, preferably hot, before breakfast; above all regularity in going to stool at a certain time every day. Purgatives should not be administered in a routine way; an occasional gentle laxative may be of use to stimulate peristalsis. A general nervo-muscular tonic is indicated, such as nux vomica or strychnine, either alone or combined with iron, aloes, belladonna, and ipecac. In more obstinate cases it may be necessary to use tonic injections, such as extract of rhatany dissolved in alcohol, once a day. He cautioned against large injections of warm water.

The Treatment of Diabetes by Uranium Nitrate.—Dr. Ebenezer Duncan, of Glasgow, in a paper on this subject, said that ten to fifteen grains had been given by Dr. West in the London Hospital with rather favorable results. Very little has been done in other hospitals. In dogs, cats, rabbits, uranium nitrate produces a nephritis. Doses up to fifteen or twenty grains in the human patient produce no bad results and may be used for two or three months.

Dr. Tyson said it was twenty years since he had used the drug until last fall, when he tried it again in much larger doses; two grains three times a day being the old dose. This last time he gave five grains thrice daily. In his cases diarrhœa often resulted and his results had not been good.

Dr. Saundby said that in his experience uranium was not a specific, but it did good in some cases, although he had not given such large doses as fifteen grains, but had given ten grains thrice daily. Dr. Duncan, in reply, said he did not consider it a specific; he simply had stated what occurred when the drug was given in his cases.

Third Day—Friday, September 3d.

Gall Stones.—Dr. William Hunter, of London, opened the discussion on cholelithiasis, dealing principally with the causation of that affection. He said the disease was a very common one, affecting nearly seven per cent. of the population. During the preceding half century very little had been found out about it, but recently some light had been thrown on the subject. Obstructed circulation has long been known to be a potent factor in the production of gall stones. Bile is a fluid of low specific gravity, composed of water which holds certain specific constituents formed by the liver cells in solution, together with bile pigments and bile salts. Certain additions are made to the bile in its passage along the bile ducts and canals. The secretion of these passages, though formerly considered a mucin, is really a nucleo-albumin. The bile also contains a small amount of cholesterin which is held in solution by the bile salts. The nucleo-albumin is secreted constantly in the gall bladder, but most actively four or five hours after food has been taken. During digestion the exit of the common duct is closed and the fluid is driven back into the gall bladder. Gall stones as a rule are composed of a centre of bilirubin and calcium surrounded by cholesterin. Cholesterin is a substance found abundantly in many tissues of the body very widely distributed. The cholesterin of bile stones is secreted in the liver cells or is a product of degeneration of the epithelial cells of mucous membranes. In bile only a very small quantity is present, while in phthisical sputa it exists in abundance. The inflamed mucous membranes of the biliary channels and gall bladder are in a great measure the sources of the cholesterin of the gall stones. Bilirubin and calcium are found free in

bile, but do not form combinations with each other in health. Free albumin will precipitate them as an insoluble mass of bilirubin and calcium. In inflammation of those passages the necessary amount of the albumin is present for that precipitation. The catarrh may be caused by the stagnation of bile which occurs in many conditions, *e.g.*, pregnancy, tight lacing, indolent habits, constipation, etc. This stagnation was not sufficient in itself to excite inflammation, as the bile is an aseptic fluid, but it is very liable to infection by the bacillus coli communis from the intestine. This is not the only organism found here, for the typhoid bacillus has frequently been found in an inflamed gall bladder existing with typhoid fever. The chief indication of treatment is to flush the bile passages. This can be accomplished in the following ways: (1) Taking food; (2) Presence of bile salts; (3) The only drug which would thin and increase the amount of bile was salicylate of sodium. It is better given in combination with Karlsbad and Vichy waters. No drug has any effect in dissolving stones except olive oil, but this, when given internally, has not effected the desired results.

Dr. W. Osler, of Baltimore, spoke of the relation of typhoid fever to cholelithiasis. The typhoid bacillus may exist in the body without causing typhoid fever, resembling in that respect the pneumococcus. In one case under observation the bacillus was found in a case of cholecystitis in pure culture without any previous history of typhoid fever. Orth, of Neusser's clinic, said there was an acute infection in cholelithiasis—enlargement of spleen, albumin in the urine, etc. Sometimes no gall stones are found, as in a case operated on by Mayo Robson. The term "hepatic intermittent fever" should be limited to cases in which a long series of malaria-like attacks occur, which may be followed by jaundice; in the intermissions the patient is perfectly well. The stone is probably in the common duct in those cases. Suppurative fever. This gives more alarming symptoms—chill, rigors, etc. Dr. Osler said that a great deal of our knowledge of this interesting subject is due to many of the recent excellent papers by the surgeons.

Dr. H. Handford, of Nottingham, Eng., said he had had a large number of cases of typhoid fever but had never observed jaundice with that disease and he thought the condition must be rare. In young people gall stones occur but rarely, but he had seen a case in a young girl. He saw a girl three years ago who had had intense jaundice one and a half years and she was still well, though the jaundice was very marked. In biliary colic very many cases are not associated with the passage of gall stones, and hence it is infrequent to find these bodies in the stools. Morphine is unsafe when there is intense jaundice and it should be given, if at all, carefully.

Dr. Baumgarten, of St. Louis, said that, with regard to gall stones and cancer, in many cases the cancer was the primary condition and the gall stones developed secondarily, but the reverse might occur. He reported a case of peritonitis following perforation, in which, after death, a very small rupture, pin point in size, was found, but there was no evidence of ulceration. The gall bladder was contracted.

Dr. Pasteur, of London, Eng., spoke of the very great difficulties of diagnosis in these cases. He reported a case in which a man of fifty-two years had had a very acute attack of colic with severe hæmatemesis. He lost flesh rapidly. No enlargement of the liver or gall bladder could be made out. The speaker advised an operation, but no stones were found. The liver was contracted as well as the gall bladder. After operation, however, the man improved very much.

Dr. Rogers, of Denver, mentioned a case in which a young girl became suddenly attacked by colic and rigors. The attacks recurred. On operation there was found a contraction of the gall bladder. The operator connected the gall bladder with the small intestine by means of Murphy's button; death followed on the second day. He expected to find peritonitis at the autopsy, but instead found an obstruction at the lower part of the small intestine. The site of operation was healthy.

Dr. Acheson, of Galt, Ont., said that there was a large quantity of lime salts in the water around Galt, and he had observed that many of his patients suffered from bilious attacks. He asked Dr. Hunter if the excess of lime had anything to do with the biliousness.

Dr. Stephen Mackenzie, of London, Eng., spoke of the importance of the investigations of Dr. Hunter. A most important fact was the relationship of gall stones with typhoid fever. He said Osler had shown that typhoid bacilli might be present in the bile without producing any inflammation of the bile passages. The fact that no calculus can be found in the fæces does not prove that none has been passed. In a case in which Dr. Mackenzie had diagnosed gall stones nothing was found on operation. Subsequently another attack occurred and about one year later the patient came to him in triumph, showing a stone which she claimed to have passed.

Dr. Hunter, in closing the discussion, said he did not think the association of typhoid fever with jaundice was common, but that it did sometimes occur. The typhoid bacillus, however, had frequently been found in the gall bladder when stone existed. The bacillus coli communis was much more common. He said there was no conclusive evidence that an excess of lime in the drinking-water would produce cholelithiasis, for gall stones occurred frequently in places where no lime existed in the water.

Pneumonic Empyema.—Dr. Angus Mackinnon, of Guelph, Ont., read a paper on the empyema of pneumonia. He thought many cases of so-called abscess of the lung were nothing more or less than a localized empyema which had opened into a bronchial tube. He considered the empyema to be due to the pneumococcus in the majority of cases. He cited several cases of this affection which he had successfully treated.

Medical Uses of the Roentgen Rays.—Dr. Francis H. Williams, of Boston, read a paper on this subject. Charts were shown illustrating the various organs in their normal position in the healthy body and then those of various diseases such as tuberculosis, emphysema, pleurisy, etc., which had been obtained by means of the fluoroscope. The excursions of the diaphragm in ordinary and deep inspiration were well marked. When a pleural effusion displaced the heart, he said, that displacement could plainly be seen. The fluoroscope outlined the shape of the heart and aorta quite plainly, so that aneurisms or other diseases could often be detected when auscultation and percussion gave no signs. Early tuberculous deposits in the lungs could often be seen when percussion and auscultation revealed nothing.

The Use of Terms to Indicate Myocardial Changes.—Dr. James Tyson, of Philadelphia, read a paper on this subject. The importance to the clinician and experimenter of using the same terms to indicate like conditions is illustrated by the term "dilatation" as applied to the heart. The word may be applied (1) to a condition of distention or stretching possible within limits in an organ whose walls are normal, when overfilled with blood, such as occurs in an early stage of insufficiency or stenosis or increased blood pressure from any cause; or (2) to an organ which has yielded as the result of pathological weakness. This may be acute or chronic, commonly it is chronic.

To such pathological enlargement the term dilatation should be restricted, while for the former the word distention is more suitable. It is the first which precedes hypertrophy, while the second succeeds upon hypertrophy. The first stimulates hypertrophy, while the second is the result of failing nutrition in a hypertrophied heart. As such, the term dilatation of the heart should be limited to a relative enlargement of one or more of its cavities associated with fatty degeneration of its walls and consequent weakening of contractile power. Such walls may be thicker than the normal walls, though they are usually thinner. Whence it is doubtful whether the term hypertrophy with dilatation should be used as synonymous with eccentric hypertrophy, for in the latter condition the muscular integrity is unchanged, or at least not degenerated. For this, the term hypertrophy with expansion might be used, the term expansion to imply no degeneration and an active state, while dilatation implies at once degeneration and passiveness.

SECTION IN OBSTETRICS AND GYNECOLOGY.

First Day—Wednesday, September 1st.

Operation of Choice in the Treatment of Pelvic Disease.—Dr. F. Henrotin, of Chicago, read the first paper. When the surgeon, he said, operates on a pus sack in this region he finds usually that he has removed the ovary. An ovarian abscess is frequently overlooked when it is the primary seat of disease. Streptococci are conveyed by certain channels directly to the ovary and an abscess forms. With free incision of the abscess and drainage complete recovery is very probable. Completeness of recovery depends on early operation. The incision usually should be made in Douglas' pouch. The speaker had made this incision in one hundred and twenty-five cases with no deaths. Pus in the ovary should be let out as well as pus in other localities. No cure is possible without operation. Early vaginal incision at any stage accomplishes good result in ninety per cent. of cases if properly carried out.

Causation and Treatment of Hyperemesis Gravidarum.—Dr. J. A. Temple, of Toronto, read a paper on this subject. The great majority of the views regarding vomiting of pregnancy are speculative. It is much more frequent in primigravidæ. The simple morning sickness is functional, but pernicious vomiting is associated with some pathological process. The fatality is probably greater than the records would show.

Most writers think it is due to reflex irritation—the nerve endings in the uterus and ovaries being disturbed in the morning by the sinking of the abdominal organs. Another view is that the cause is pressure of the growing uterus. Stretching of the os has been beneficial in some cases. Gastric and intestinal ulcers are also said to cause the vomiting of pregnancy. A centre akin to the vomiting centre in the medulla has been made out.

Dr. Giles, of London, said he agreed entirely with Dr. Temple. There had been no sickness in thirty-three per cent. of his cases. He considered vomiting pathological and not physiological. In fifty per cent. there was no sickness in the first three months. The most striking characteristic was the association of dysmenorrhœa, and hence he connected the nervous system with this condition.

Dr. William Gardner, of Montreal, said his experience had been that after the uterus had been emptied the patients made rapid recovery. Dilatation of the cervix may stop the vomiting at once, but it frequently fails. The bougie method may also fail and then rapid dilatation of the cervix must be performed.

Dr. I. M. Lawrie, of Weymouth, Eng., said he had not been able to find sufficient pathological conditions, displacements, etc., to account for the vomiting. A good rule which he had followed was always to have a consultant with him before inducing an abortion. He regarded rapidly increasing pulse and the dark brown and black vomit as dangerous symptoms and indicating the time for operation. He usually tamponed the lower segment of the uterus for twenty-four hours and allowed labor to go on the next day.

Dr. Skene, of Brooklyn, said he recognized the fact that long-continued functional disturbance might lead to some pathological condition. He believed in using nervous and gastric sedatives first and in the event of failure emptying the uterus. Lavage of the stomach he had tried with success in some cases.

Dr. Harris, of New York, considered the treatment of this condition should always be carried out with regard to its etiology. Erosion of the cervix requires application of nitrate of silver and in many instances the case may be tided over without emptying the uterus. Slow dilatation by gauze packing remaining in utero over night is better than the rapid method.

Dr. Charles Jewett, of Brooklyn, regarded bromides and chloral as the best sedatives administered per rectum. It was imperative to operate before the stomach became much diseased.

Dr. J. C. Cameron, of Montreal, said no rule of treatment can be formulated in this condition. We treat our patient, not the disease. Interference is imperative before the patient's vitality had become so impaired as to render the operation useless. He agreed with Dr. Giles regarding the causation of this condition.

Second Day—Thursday, September 2d.

The Injuries of Parturition, the Old and the New.—Dr. W. Japp Sinclair, of Manchester, Eng., chairman of the section, said that he had selected the subject of his address because of the frequency with which, as a gynecologist, he had been called upon to deal with injuries produced by parturition, and the growing conviction that in many, if not in the majority of those injuries, their existence has not appeared to be altogether satisfactorily explained as inevitable, and not a few have been proved by irrefragable evidence to be produced by operative proceedings altogether unwarranted by the circumstances.

Some time last year he was asked to see a young primipara who was very ill toward the end of the first week of the puerperium. He was informed by the practitioner in charge that the case had been quite straightforward, from first to last, and the latter could not in any way account for the patient's condition. On making a physical examination without moving the patient from the dorsal position, the speaker discovered a deep and wide laceration of the vaginal vault; the examining finger passing easily into the tissues of the parametrium. No mention of forceps was made in the conversation before seeing the patient, and it was only after the examination and in reply to a question, that the attending physician explained why and when they had been applied.

A few years ago he made several repairing operations on the injured pudenda of a young married woman. She had been by all accounts perfectly sound and active a year before, but meanwhile she had got married and she had become a mother. The uterus was found to be completely prolapsed, and it was so lacerated that the anterior and posterior halves of the cervix projecting from between the nates looked like two separate organs, and the perineum was torn completely through into the anus. This patient then suffered from dislocation of the uterus, transverse

laceration of the cervix, and complete rupture of the perineum. She was treated by Emmet's operation, restoration of the perineum, and shortening of the round ligaments, and then she was fairly comfortable with a pessary. It was learned afterward that this case had been one of normal labor in a primipara, and that the delivery had been effected instrumentally within six hours from the commencement of the pains. Comparing this sort of practice, still possible at the present day, with what occcurred in a former age, attention was directed to the teachings of Mauriceau. From these a glimpse was given of the helplessness of the seventeenth century in the practice of obstetrics. With the resourcefulness at the end of this nineteenth century it may still be alleged, not without reason, that there is to be seen in the contrast only one more illustration of how "knowledge comes, but wisdom lingers." The results of our modern practice do not make it so perfectly obvious that in obstetrics we are much wiser than our sires. While we have much to congratulate ourselves upon, yet we may fairly ask if there is not much room for improvement in the use which we make of our resources. He thought that a warning note should be sounded against the too free application of surgical methods in gynecological practice. Surgical interference in midwifery practice was the great provider of surgical work for the gynecologist. In addition to the avoidable childbed mortality, there is the very serious question of childbed morbidity, which is largely owing to the abuse of the forceps in the practice of midwifery.

After reviewing the practice as outlined by Smellie in the seventeenth century, reference was made to the influence on obstetrics by Simpson's introduction of anæsthetics. Next came the combination of anæsthetics and antiseptics and the triumphs of abdominal and pelvic surgery applied to the diseases of women. After strongly protesting against the meddlesome and mischievous midwifery for which some reform, he thought, was urgently required, figures were given showing the details of two years of practice at Manchester Maternity Hospital. From these it was seen that the forceps deliveries were about 1.4 per cent. in charity cases, but within the same area of population, and among the class of people who could afford to pay for private medical attendance, the proportion of forceps deliveries was from twenty to thirty per cent. Such a striking contrast surely supplied food for reflection and called for explanation. Experience now points to the fact that we have replaced the one great injury of parturition in former generations—vesico-vaginal fistula—by a host of others, vesico-vaginal fistula by laceration instead of by sloughing included, and it is only reasonable to conclude that there must be something seriously wrong with our theories or our practice, or with both.

Treatment of Fibroids of the Uterus by Vaginal Ligature of the Broad Ligament.—Dr. Franklin H. Martin, of Chicago, read a paper on this subject. He advocated the operation in cases of interstitial and intramural fibroids and considered it much preferable to hysterectomy. He passed a double silk ligature round the broad ligament about one inch from the uterus, and including the uterine artery. This operation was usually successful in bringing about such atrophy of the fibroid that parturition might go on as usual.

Dr. Hiram Vineberg, of New York, submitted statistics showing a total failure of the operation in his series of cases.

Dr. Skene, of Brooklyn, advocated curettage of the uterus as a proceeding absolutely necessary along with Dr. Martin's operation. He laid great stress on the treatment of the attendant endometritis.

The Vaginal Versus the Abdominal Route in Dealing with Inflammatory Conditions and Tumors in the Pelvis.—Dr. E. W. Cushing, of Boston, read this paper. The selection of either method depended much on the personal equation of the operator; some surgeons being proficient in one of the methods, some in the other. Some points in favor of the vaginal route were the absence of a cicatrix, the slight degree of shock, and the lessened liability of wounding the intestines and other abdominal organs. He advocated the removal of fibroid tumors through the abdomen. For the cervix the vaginal route was preferable and always when the thickness of the abdominal wall rendered the suprapubic operation difficult. For pyosalpinx with removal of all the appendages either route was available.

Dr. Skene, of Brooklyn, said he advocated twenty years ago the employment of the vaginal route and consequently was pleased to see modern operators returning to his ideas.

Dr. Hanks, of New York, entered a protest against the practice of attacking a ruptured tubal pregnancy through the vagina. He cited two instances in which uncontrollable hemorrhage resulted, apparently from the tube of the opposite side.

Dr. Ross, of Toronto, entered a strong protest against the adoption of the French method of operating per vaginam and said he still was a warm advocate of the older and safer abdominal route.

Third Day.—Friday, September 3d.

Diagnosis and Treatment of Intrapelvic Tuberculous Disease.—Dr. Ross, of Toronto, presented a paper with this title, in which he gave it as his opinion that in the great majority of these cases tuberculosis of the intestines coexisted. Only one case had come under his notice which showed no intestinal disease. He discussed the diagnosis of this affection very thoroughly and laid great stress upon the value of the clinical thermometer in distinguishing these cases from hysterical manifestations. With reference to treatment he was disposed to doubt the theory that air was the curative factor, because, if this were so, why were the lungs and pleuræ so frequently affected with tuberculosis? He advocated abdominal section in the great majority of cases. If late operation is advisable, so much the more so is operation in the early stages of the disease. He considered the cessation of menstruation and relief of congestion, consequent upon removal of tubes and ovaries, as a most important factor in the cure.

Conservative Treatment of the Ovary.—Dr. Howard Kelly, of Baltimore, sent a paper which was read, in his absence, by the secretary, Dr. Giles. He entered a strong plea against the modern practice of removing every vestige of ovarian tissue unnecessarily. Coupled with the discussion on this paper was one by Dr. T. More Madden, of Dublin, on the conservative treatment of Fallopian-tube disease.

Dr. A. P. Dudley, of New York, said he made it a rule to leave behind as much of the ovary and appendages as is consistent with the cure of the disease. He had removed half an ovary, scraped out cysts, and removed one ovary and one tube in cases in which modern practice would lead one to deprive the woman of all her genital organs.

Dr. Gordon, of Portland, Me., protested against the ultra-conservatism of leaving the uterus after removal of the appendages. All cases did better when complete removal was persisted in.

Dr. Giles, of London, Eng., deplored the absence of statistics showing the ultimate result of these operations, as this, he considered, was the only true manner of determining their efficacy or otherwise.

Diagnosis and Treatment of Retroversion of the Uterus with Fixation.—Dr. A. Lapthorne Smith, of Montreal, read this paper. He thought the subject of displacements was often treated too lightly by most men, but he wished to call attention to the importance of this subject. Palliative measures were advisable to begin with, but radical treatment was in many cases necessary. This comprised the two operations, ventral fixation and Alexander's operation, the technique of which he described.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

LUNACY IN SCOTLAND—PRESSURE ON ASYLUMS—PECULIAR PEOPLE—BABY FARMING—FATALITIES IN THE PROFESSION—BLACK SHEEP—AMERICAN JUBILEE FUND—MORTALITY RETURNS.

London, September 10, 1897.

The Scotch lunacy commissioners have just issued their blue book, in which the statistics show that in Great Britain the increase of certified lunatics is as noteworthy in the northern kingdom as in the southern. No doubt much of the increase is due to causes similar to those in England. The remark of Dr. C. Macpherson in his last report, that "a wider view is now commonly taken of what constitutes insanity, or at least certifiable insanity, than was the case twenty years ago," sums up the situation. Nevertheless the progressive figures are calculated to give uneasiness and to foster the alarm felt by some. On January 1st of this year the number of certified lunatics in Scotland was 14,086, approaching to double the number in 1874, viz., 7,885. A continuance at the same rate will certainly show that in a quarter of a century the number will have doubled. The increase has been more rapid of late. Thus it took four years to add the eighth thousand to the number of 1874 just quoted. In eight years the tenth thousand was passed, so that in 1886 there were 10,895. But by 1895 there were 12,950, and in 1896 no less than 13,703, while, as stated above, on the 1st of January last there were 14,086.

The great bulk of the increase was naturally in pauper lunatics, as their wants are met by the law. In fact, the poorer class of private patients is less provided for, as between the rich and the pauper classes the accommodation of the asylums is fully taken up. Contracts have been entered into for the reception by the asylums of the paupers of certain districts, while the excellent provision attracts wealthy patients from a distance—even from England and Ireland. This accounts for the difficulties of the less affluent private patients in finding accommodation, and it is suggested that legislation might meet the case by authorizing district boards to provide for such private patients.

A coroner's jury has returned a verdict of manslaughter against one of the "Peculiar People"—a sect which is founded on the literal interpretation of a passage in St. James' Epistle, directing the elders to anoint the sick, etc. These people therefore refuse all medical aid to themselves and their children. The coroner told the father he was bound by law to call in a doctor, and, if his neglect to do so accelerated death, he was liable to punishment; his religion had nothing to do with the matter. Evidence was offered that medical aid would have prolonged the child's life. As the father is committed for trial, we may expect an authoritative statement of the law on the subject.

The county council seems to be exercising its control over baby farming with commendable vigor. The annual report of the committee charged with this work shows that under the act sixty houses were registered during the year for keeping infants. A watch was kept on newspaper advertisements offering to take infants, many were answered, and the cases followed up. The inspectors, it seems, keep in touch with the police, the registrars of births and deaths, and with other officials whose duties bring them into contact with infants separated from their parents. In all, twenty-four hundred and thirty-seven reports were made as to the investigations made by the inspectors during the year, and fifteen persons were found to have broken the law. Proceedings were taken against four of these, but it does not appear why the others should not have been prosecuted. It is the fear of prosecution which is the chief deterrent, and, as it is generally admitted that the law is good, I fail to see why the council should not take proceedings in every case of breach of the law.

Some sad fatalities have lately occurred. Dr. Starkey Smith, of Warrington, expired suddenly while attending to a patient. He was well known and was a magistrate for Warrington. Dr. E. Barber, of Sheffield, also died suddenly as he was leaving the dining-room after dinner. He was only twenty-nine years old. Dr. Wyllie, of Elie on the coast of Fife, met with his death by drowning while bathing last week. He was an expert swimmer, but was apparently seized with syncope or cramp, and carried away by a current before assistance could reach him. The wife of Dr. Bryan, of Northampton, has also met a tragic end under strange circumstances while returning home by rail. She was last seen alone in a first-class carriage, but on its arrival the carriage was found empty. Search along the line was made, and the body found horribly mutilated. Dr. Lammiman, of Tunbridge Wells, was in a railway accident when four carriages rolled over an embankment. He escaped with minor injuries in an unaccountable manner, and after recovering from a dazed state was able to render his services to those who were more injured.

Sadder, in one sense, are cases in which doctors have been charged with fraud or crime. There is one now under investigation, in which a charge of wholesale swindling by a surgeon in conjunction with a "titled lady" is made. Another surgeon is accused of bigamy. The details are unsavory. Such aggravated cases are sometimes cited as a disgrace to the profession, but they are very few in proportion to the numbers on the register when compared with other classes of the community. Still every one is to be lamented, and one can only say with the old proverb, "There are black sheep in every flock." When they are mentioned to me, I point to the great roll of those of the profession whose names are everywhere honored as among the benefactors of the race and "the excellent of the earth."

The committee of the American Victoria jubilee fund has sent £1,000 to Guy's Hospital, to endow in perpetuity a "Queen Victoria bed." Another sum of like amount has been sent to the London Hospital on the same condition, and a third thousand to Charing Cross Hospital.

The London mortality last week was twenty per thousand, including in the total deaths twenty-eight from diphtheria. There was no death registered from small-pox in London or any of our large towns.

Tinea Favosa.—After washing with green soap and shaving the scalp apply:

A SCHOOL FOR FAVUS CHILDREN.

To the Editor of the Medical Record.

Sir: In the hope that it may be possible to secure educational facilities for the large number of children excluded from the schools by the recently organized system of inspection, I ask for a brief space in the Medical Record and bespeak its influential co-operation. Several years ago I began to realize the dangerous increase in the number of contagious scalp diseases in the public schools, and sought to interest the school authorities in the matter of establishing some system of inspection and exclusion. When the present system to shut out contagious diseases was put into operation, I was much gratified to learn that the scalp was to come in for its due share of scrutiny.

The result has been that already dispensaries in certain quarters of the town are overrun with ringworm, pediculosis, and favus cases, detected and sent home by the wide-awake school inspectors. Naturally few of the favus-affected children can or should be allowed to return to school for a year at least, even if they can be forced to carry out treatment; while many with scalp ringworm cannot get a clean bill of health for perhaps a like period, or at least for many months.

It is for this class that I would urge the establishment of one or more schools, where not only can their education be continued, but where treatment can be inforced until a permanent cure is established. As conditions now exist, there is danger of driving these children out of the schools into occupations in which their affections will still endanger others.

So far as my personal experience goes, it is extremely difficult to keep victims of favus sufficiently long under treatment outside of or even in an institution if parents can remove them at will.

Charles W. Allen, M.D.

[illegible] East Sixtieth Street.

THE SOCIAL SIDE OF THE MOSCOW CONGRESS.

(From our Special Correspondent.)

St. Petersburg, August 21, 1897.

The series of social events arranged to make the stay of the members of the International Medical Congress an agreeable one came to a close to-night with a reception given by the physicians of St. Petersburg in the Nobles' Club. The three days since the close of the congress have been crowded with social events gotten up for the visitors. There was an excursion to the islands by steamboat on the Neva and the Grand Nevka on Saturday afternoon, with the promenade in the botanical gardens, at which many of the highest Russian aristocracy were present and the wants of the inner man not forgotten. On Sunday afternooon there was an excursion to the palace at Peterhof, with the view of the grounds, the palace, and the magnificent fountains, and a royal spread for which the two hours' ride over the Gulf of Finland had properly whetted the appetites of the invited guests. Then on Monday, beside the soirée, there was lunch at the Institute of Experimental Medicine and a chance to see the magnificent laboratories for experimental research in everything connected with medicine that are here so perfectly equipped. All this in a city almost a thousand miles away from where the congress was held, the railroad tickets to and fro costing nothing and many of the visiting doctors being lodged absolutely free of expense in various public institutions of the capital. It is a fitting climax to the succession of agreeable surprises that Russian hospitality has prepared for her medical visitors since they reached the frontier. Most people were a little anxious about how this putting one's self into the grasp of the Russian bear was going to turn out; but from the moment when at the frontier the medical committee smoothed out all difficulties as to passports, luggage, and customs, there has been coming the gradual realization that bruin's hug is a hearty, cordial one, and eminently friendly and hospitable. This has been true not in Moscow and St. Petersburg only, but everywhere that members of the congress stopped for even a day. Visitors from the south cannot speak highly enough of their cordial reception by the committee at Odessa or of their pleasant hours in Kiev, the Jerusalem of Russia, under the friendly care of brotherly and (may we add?) sisterly solicitude. It was the same thing at Warsaw and at points off the main lines where members stopped for a day or two.

The arrangements at Moscow itself were excellent, and too much cannot be said in praise of the general committee for the excellent way in which it accomplished the immense task of handling the ten thousand visitors to the congress. The Manége—a huge building meant for manœuvres and about five hundred by one hundred and twenty feet—made an excellent place of reunion for the midday lunch, where one could meet one's friends and learn the news. The magnificent Imperial Theatre, with a seating-capacity of over four thousand, made an ideal assembly hall for the general sessions and such as could be supplied by but few cities of the world.

The general impression produced on the members of the congress is an excellent one, and every one is perfectly free in confessing how agreeably he has been surprised by the extent to which Russian hospitality has gone in providing entertainment for us. We have been the nation's guests and have been made to feel it. Every Russian seems to have felt it a personal duty to do his little mite to help produce a favorable impression on the Western visitors, who for the first time found themselves in considerable numbers in his supposedly Oriental country. The cordiality of the people was noteworthy, and manifested itself in the extremest readiness to be of help when the difficulties of the Russian tongue paralyzed our efforts at being understood by cabman, shopkeeper, or passerby. Without exception, it is with feelings of deepest appreciation for all this, and of lasting gratitude for kindness from our "stranger hosts," that the members of the congress take their leave.

But we have learned more than the lesson of gratitude. We have seen the magnificent medical institutions of Moscow and St. Petersburg, and we have learned to appreciate how much the Russians are doing for scientific medicine. Moscow, after all, most of us thought of as a thoroughly mediæval place, whose hospitals and clinics doubtless smacked of antiquity. The visit to the university clinics was a revelation—one after another piles of magnificent buildings, none of them more than ten years old, all of them thoroughly up to date; the gynæcological and ophthalmological clinics and the Pathological Institute, beautiful structures architecturally and arranged to facilitate the very best scientific work in these branches, all of the university clinics spread out over acres and acres of ground, magnificently lighted, airy, and comfortable, up to date in every respect.

Here in St. Petersburg was the same story almost to tell. Money has been no object in providing clinical, scientific, and teaching facilities of the highest order—the culmination of it all to be seen in the magnificent Institute of Experimental Medicine, which has nothing to compare with it in the world. Here, on ample grounds on a large arm of the river, is a series of buildings, all with one exception erected for the purpose, in which all branches of science connected

with medicine may be studied practically. Everything —materials, cultures, even animals—is supplied and cared for by the institute; the student works under the direction of a distinguished professor, and the charges for the year are only 25 rubles ($13)! The internal arrangements, the mechanical appliances, even to railways and elevators for the transportation of animals, the bathing and sterilizing apparatus, the operating-rooms, the kennels—everything is most perfect and nothing seems to have been forgotten.

Can anything good come out of Russia? the medical scientific world might have asked some years ago; but now the answer to the question is obvious: some of the best scientific work is being done here. The Western visitor to the congress was sometimes, I think, conscious in the applause given at the sections, and in their relations to one another outside, of a closer bond of union between the Russians, the Poles, and the Bohemians, than between the other members. They are the representatives of the Slav races of Europe to-day. There is an impression among them that the future is theirs. The Celts and the Teutons have had their day, and are degenerating; the descendants of the Romance nations need scarcely be counted with at all; and so must come from the East once more a people whose acme of culture, civilization, and science shall represent the latest step in the world's evolution. Such is their dream.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending September 18, 1897:

	Cases.	Deaths.
Tuberculosis	268	[illegible]
Typhoid fever	33	[illegible]
Scarlet fever	65	[illegible]
Cerebro-spinal meningitis	1	3
Measles	28	[illegible]
Diphtheria	119	21
Laryngeal diphtheria (croup)	2	1
Chicken-pox	1	

Medical Practice in Washington.—There have been much discussion and correspondence in regard to the custom of some town doctors visiting health resorts in New England and there practising. The resident medical men have complained loudly of the injustice of this procedure. A Washington correspondent of the *Atlantic Medical Weekly* presents in a long letter the reverse of this picture, that is to say, the view of the question as taken by a town physician. From the subjoined account it would seem that the lot of the average medical man is not a happy one. "Boston practitioners complain of oversupply because of one physician for every five hundred inhabitants. Here we have one for every two hundred, not to mention numerous "sundowners," faith curists, Christian scientists, and other advertising charlatans. Bright men, with the qualifications of both home and European education, are languishing at the prospect before them of conspicuous failure and are not making enough to supply the bare necessities of life. I know of one poor struggling fellow, a qualified man of good habits, who passed Christmas week with no gas or coal in his house, while he and his family subsisted during that season on corn meal and hot water exclusively. Next to the free-dispensary abuse which we have with us in full-blown proportions one of the most serious things a Washington physician has to contend with is the matter of collections. It is said that the laws of the district seem to have been framed with a view to prevent the collection of honest debts. Add to this the fact that the pay of government employees cannot be attached or garnisheed, and the virtual protection afforded them by heads of departments almost places a premium on dishonesty and increases the difficulty among many victims. I know of one practitioner who has more than three thousand dollars in small bills which he cannot get from delinquent government clerks."

The First Medical Degree in New England.—Dr. Francis R. Packard writes in the *Journal of the American Medical Association* that the first medical degree granted in these parts was an honorary one, bestowed on Daniel Turner, of Connecticut, by Yale College in 1720. As this was intended as a token of gratitude for Dr. Turner's liberal gifts to the college and not as a recognition of any particular fitness on his part to practise medicine, a wit of the time interpreted M.D. to signify *multum donavit.*

Smoke.—At a debate on smoking, among the members of the British Association, many speakers denounced and others advocated the practice. Professor Huxley said: "For forty years of my life tobacco has been a deadly poison to me. [Loud cheers from the antitobacconists.] In my youth, as a medical student I tried to smoke. In vain; at every fresh attempt my insidious foe stretched me prostrate on the floor. [Repeated cheers.] I entered the navy; again I tried to smoke and again met with a defeat. I hated tobacco. I could almost have lent my support to any institution that had for its object the putting of tobacco smokers to death. [Vociferous applause.] A few years ago I was in Brittany with some friends. We went to an inn. They began to smoke. They looked very happy and outside it was very wet and dismal. I thought I would try a cigar. [Murmurs.] I did so. [Great expectations.] I smoked that cigar; it was delicious! [Groans.] From that moment I was a changed man; and now I feel that smoking in moderation is a comfortable and laudable practice, and is productive of good. [Dismay and confusion of the antitobacconists. Roars of laughter from the smokers.] There is no more harm in a pipe than there is in a cup of tea. You may poison yourself by drinking too much green tea and kill yourself by eating too many beefsteaks." [Total rout of the antitobacconists and complete triumph of the smokers.]

Dipping Cattle as a Remedy for Texas Fever.—A somewhat novel series of experiments is being tried in the case of cattle suffering from Texas fever, and one which is stated to have been followed by most satisfactory results. For some considerable time there has been in Kansas a rigid quarantine against cattle from the Texas-fever district. It has lately been discovered that ticks were the means of spreading the contagion, but that by dipping the cattle these have been got rid of. The experiments of dipping cattle for the destruction of ticks were undertaken at the agricultural experiment station of the University of the State of Missouri, at Columbia, Mo. Mr. R. I. Kleberg, the manager of the Santa Gertrude ranch, constructed a dipping-vat large enough to allow the complete immersion of a full-grown animal. Many preparations of different kinds are used in which to dip the cattle, the most successful being a mixture of certain oils containing a small proportion of carbolic acid. At Fort Worth the cattle are being dipped in chloro-naphthol. The experiment there is being conducted by the department of animal industry.

KATATONIA (KATATONIE OF KAHLBAUM—KATATONISCHE VERRÜCKTHEIT OF SCHÜLE).[1]

BY FREDERICK PETERSON, M.D.,

NEW YORK,

FORMERLY FIRST ASSISTANT PHYSICIAN AT THE HUDSON RIVER STATE HOSPITAL FOR THE INSANE; CLINICAL PROFESSOR OF INSANITY IN THE WOMEN'S MEDICAL COLLEGE OF THE NEW YORK INFIRMARY; CONSULTING PHYSICIAN TO THE MANHATTAN STATE HOSPITAL FOR THE INSANE;

AND

CHARLES H. LANGDON, M.D.,

POUGHKEEPSIE, N. Y.,

SECOND ASSISTANT PHYSICIAN AT THE HUDSON RIVER STATE HOSPITAL FOR THE INSANE.

History.—Katatonia, derived from the Greek word *κατατείνω*, meaning "I stretch tightly," is a term applied to a certain group of psychical and motor symptoms presently to be described, which has often been considered as constituting a new and distinct form of insanity. There is, however, a great diversity of opinion in regard to this. This opinion was first held by Kahlbaum, of Görlitz, who wrote and discussed the subject fully in a monograph which he published in Berlin in 1874. Dr. Kiernan, in an article on katatonia, published in 1882, mentions that Meynert, two years before Kahlbaum, described the syndrome as a "peculiar form of melancholia attonita," as "characterized by a series of fluxionary excitations, toned down by coexistent cerebral pressure, microscopic exudations, ventricular dropsy, and perhaps premature ossification of the sutures. From these will result forced and theatrical activities on the part of the patient. The convulsive state indicates the control of the irritative factors; the cataleptoid conditions, the triumph of the depressing factors. The ideas of grandeur following upon stupor are the results of ideas previously caused by fluxionary conditions."

Katatonia has been defined by Spitzka (1883) as "a form of insanity characterized by a pathetical emotional state and verbigeration, combined with a condition of motor tension." To this Dr. Nolan would add, "running a quasi-cyclic course of expansion, hysteria, and stupor," stating that this "would help to define the disease in unmistakable terms."

Katatonia commences with headache, usually occipital, insomnia, a general feeling of mental distress and uneasiness, followed sooner or later by an attack of convulsions, epileptiform in character, or a condition of excitement or melancholia agitata. This is soon followed by a condition of rigidity and immobility—the "attonita" stage. Recovery may now take place or the patient may drift into a condition of terminal dementia. As already stated, authors and alienists are not in accord as to whether katatonia should or should not be placed as a distinct form among mental diseases. The following are some of the most important opinions that have been expressed on this subject:

Dr. Arndt, in a paper read before the meeting of the Psychological Society of Berlin, 1874, said that he agreed to an extent with Kahlbaum's theories, but that he did not accept katatonia as a new form of psychic disease. He said that katatonia may have the most varying causes and relations, and cannot therefore be considered a special form of disease.

Dr. Ewald Hecker says that Kahlbaum's statements and clinical diagnostic methods are excellent and reliable, and he discusses the subject in full, its etiology, symptoms, etc., and he reports two cases in a paper which he published in the *Allgem. Zeitschr. f. Psych.*, vol. 33, 1877. In the same volume of the *Allgem. Zeitschr. f. Psych.*, Dr. Brosius discusses this subject. He says that the "symptomatic entity" of the mental disturbances joined together under the name of katatonia is specific, and that the separation of katatonia as a distinct form of disease is thereby justified.

Dr. James G. Kiernan, in the same year, 1877, published an article on katatonia as a clinical form of insanity, in the *American Journal of Insanity*. He considers that katatonia is entitled to a distinct place as a form of insanity, so far as frequency of occurrence gives any right to the same. He gave in this paper an account of some thirty cases. In 1882 he published an important article on this subject in the *Alienist and Neurologist*, and in 1884 a third article in the *Detroit Lancet*.

In 1878 Professor Westphal discussed this subject in a paper in the *Allgem. Zeitschr. f. Psych.*, and said that clinicians, in the effort to study and separate mental diseases, are apt to be narrow in one way or another, and that this was true of Kahlbaum in respect to his study of katatonia. He thought that Kahlbaum's katatonics were insane patients exhibiting variations in the manner of development of their insanity and variations in the subsequent course of its psychical manifestations. He did not consider the manifestations which Kahlbaum declared to be specific to be such, nor that they were entitled to a place in the clinical group. He further said that Kahlbaum "mistakenly ascribes a spasmodic character to these manifestations."

In 1878 Dr. N. B. Donkersloot wrote an article, in which he said that katatonia should be used as a name for a certain set of cases, the principal symptom being incapacity of action from disturbance in cerebro-motor centres, and stated that it often complicated nervous diseases, such as catalepsy, hysteria, epilepsy, melancholia with stupor, etc., so that to give it a special etiology and treatment was not well possible.

Dr. Tigges, in the *Allgem. Zeitschr. f. Psych.*, 1878, discussed one hundred and four cases of melancholia with stupor, and said that he could not agree with Kahlbaum's scheme of katatonia, but that it stood on an equal footing with the other forms of melancholia, and at times ran into them; that it showed the symptoms of such transition forms, and was connected, as were the other forms of melancholia, in multiple ways with other psychical groups.

Dr. von Reinecker, in a discussion published in the *Allgem. Zeitschr. f. Psych.*, in 1880, said he did not believe that katatonia should be considered a distinct clinical form of insanity.

Dr. Sander, of Dalldorf, and Dr. Mendel, of Berlin,

[1] Read before the American Medico-Psychological Association, May 13, 1897.

in the same article, expressed their opposition to placing katatonia in the list of separate mental diseases.

In 1881 Dr. Hack Tuke, in a paper on "Mental Stupor," published in "Transactions of the International Medical Congress," London, vol. 3, said he thought that Kahlbaum, in making the disorders of motility the essential part of the malady, carried his views too far. The morbid mental state conditioned the motor trouble, and it was right to take the former, not the latter, as a basis of classification. It was important, however, to bring the motor and psychical troubles into relation. In conclusion, he summed up by saying that he thought "the cataleptic variety of mental stupor (and probably other varieties also) was a condition to be regarded as caused by the exclusive direction of the mind upon a melancholy delusion; or, if this be absent, by brain exhaustion due to various causes calculated to paralyze volition and allow of involuntary action."

In 1881 Dr. M. E. Fink, in the *Allgem. Zeitschr. f. Psych.*, wrote an article recognizing katatonia and giving the differential diagnosis of it and hebephrenia. In 1882 Dr. Karl Laufenauer gave two cases of katatonia in the *Pest. med.-chir. Presse*, and this author evidently accepted Kahlbaum's definition of katatonia. In the same journal, 1882, Dr. Eugene Konrad accepted Kahlbaum's theories in part, but thought Kahlbaum went too far in considering all psychoses exhibiting katatonic symptoms as phases of katatonia.

In 1883 Dr. v. Krafft-Ebing, in the second edition of his "Lehrbuch der Psychiatrie," mentioned katatonia as a form of disease defined by Kahlbaum, made up of symptoms given by the author under a division of "Circulares Irresein." In the same year Dr. William A. Hammond read a paper before the New York Neurological Society, in which he accepted Kahlbaum's definition of katatonia; and Dr. S. V. Clevenger, in an article in the *American Journal of Neurology and Psychiatry*, on "Insanity of Children," mentioned katatonia apparently without questioning the validity of the name, and referred to Kiernan's observation of it in a boy of eleven. In this year Dr. Richard Neuendorff, in the *Centralbl. für Nervenheilk.*, reported two cases and evidently accepted Kahlbaum's definition of katatonia. In 1886 Dr. Knecht wrote on katatonia in the *Allgem. Zeitschr. f. Psych.*, and reported cases giving the differential diagnosis and also the report of two autopsies. In the same year Dr. W. P. Verity wrote on katatonia for the *Journal of Nervous and Mental Disease*. He quoted Kiernan, with whom he evidently agreed, and mentioned that Clevenger expressed the opinion that katatonia "seems allied etiologically to some rheumatoid disease, though its origin may be in nerves or blood." He cited one case of his own. In 1886 Schüle, in the *Klinische Psychiatrie*, Leipzig, gave an exhaustive and perfect picture of clinical katatonia, and divided it into three varieties—the religious expansive form, the depressed form, and hysterical katatonia. Clemens Neisser, of Stuttgart, wrote on katatonia in 1887, and also furnished a valuable article on katatonia for Tuke's dictionary.

In 1889 Dr. W. Julius Mickle furnished a long and comprehensive article on katatonia in vol. 12 of *Brain*. He believed that Kahlbaum has demanded for katatonia an application far wider than can be admitted, but conceded to it a "separate existence as at least a variety or sub-form, if not as a separate and distinct form of mental disease, for which last view there is much to be said." "At least as a symptom assemblage, or syndrome, the name katatonia will have its uses in mental medicine." He said that nosologically it should be placed as an appendix to the class of psycho-neuroses. There were elements in katatonia leading one to consider it equally well placed in the second great group of mental maladies (as classified by the author), namely, that in which hereditary influences have formed from ordinary neuroses, of "psychoses of hereditary or other morbid constitutional neurosal or mental degeneration, of defective organs, mental constitution, or of incomplete or arrested brain development." Here it might stand between the class of periodical and circular psychoses on the one hand, and on the other the adjoining class containing hebephrenia, paranoia, simple hereditary insanity, etc. He further stated that the views expressed by Drs. Séglas and Chaslin are partly similar to his own. These authors, whose writings on this subject are to be found in the *Arch. de Neurol.* for 1888, and *Brain*, vol. 12, do not accept katatonia as a distinct disease, but consider it a variety of melancholia, simple or sympathetic, with stupor more or less marked, perhaps more distinctly related to hysteria. Dr. Nicholaus Ostermayer, in the *Allgem. Zeitschr. f. Psych.*, vol. 48, expressed the opinion that clinically we must accept Kahlbaum's theories; and that, while katatonia is probably not a frequently occurring form of psychical disease, it is not one of the rarest forms.

In 1892 Dr. Edwin Goodall, in the *Journal of Mental Science*, London, published a paper entitled "Observations upon Katatonia." He was undecided as to whether katatonia should or should not be considered a separate malady. Dr. R. Percy Smith, in the *Journal of Mental Science* for 1892, cited a case of "so-called katatonia." He considered the term "katatonia" as dubious.

In 1894 Dr. E. D. Bondurant published an article on katatonia with six illustrative cases, in the *Medical News*, vol. 64. He considered katatonia a convenient name for a "rare and interesting group of symptoms."

Clouston, in his work on "Mental Diseases," 1897, states that "katatonia is simply a variety of alternating insanity, in which the functions of the motor-trophic centres are especially involved."

Bevan Lewis, in his text-book on "Mental Diseases," 1890, says: "The more closely we study these cases of katatonia described by Kahlbaum, the more convinced we are that we are not dealing with any distinct pathological entity, but with some of the multiple forms of hysteria. . . . Melancholia attonita closely approximates to the state to which we now allude."

Conolly Norman, in a monograph on "Acute Confusional Insanity," states incidentally that katatonia is probably to be regarded as a type of the above-named disorder.

We thus see that katatonia has been described variously as a clinical entity, as a variety of melancholia, as a form of circular insanity, as a type of acute confusional insanity, as a species of hysterical insanity, and by one author (Schüle) as attonic mania.

A careful study of the subject as detailed by the authorities cited, together with observations of our own, gives us the following facts in the etiology, pathology, and symptomatology of katatonia:

Etiology.—One of the most important predisposing causes of katatonia is hereditary influence. Katatonics are often members of families showing hereditary psychic degeneration. Scrofulous and tuberculous diatheses are frequently predisposing causes. The other most important predisposing causes are age and sex, the majority of cases being youthful and belonging to the male sex. Students and teachers are said to be especially prone to have this trouble. The influence of stimulants may act as a predisposing or exciting cause. The principal exciting causes are masturbation, sexual exhaustion and excess, religious and emotional excitement, mental strain, worry, anxiety, syphilis; indeed, all of the usual factors in the causation of ordinary melancholia.

Pathology.—Kiernan found that the disease is most

frequently preceded during infancy by a basilar meningeal process of a tuberculous character. Kahlbaum's post-mortems show evidences of a healed-up hydrocephalus and a basilar meningitis. Meynert's deduction from Kahlbaum's cases is that the disease has been preceded by a patho-meningeal process located at the base of the brain and over the fissure of Sylvius. Kiernan further says: "In a patho-psychological aspect the localization of the process would be over the base of the brain, in the fourth ventricle, and over the fissure of Sylvius." Dr. Julius Mickle says that the post-mortems show brain atrophy, anæmia, marked basal meningeal changes, or passive hyperæmia and œdema of meninges—all of which indicate a profound alteration of brain nutrition. The pia is at times found to be adherent in patches to the brain, and superficial layers of gray matter are separated when the membranes are stripped off. These patches are situated at the anterior part of the inferior mesial surfaces of the cerebral hemispheres. The arachnoid is slightly thickened and opaque over the base of the brain, and there are thickening and opacity over the superolateral gyri

We are inclined to believe that the more this class of cases is investigated, the greater will be the accord shown with the pathological findings in melancholia.

Kahlbaum's theory of the cause of verbigeration was that it was a kind of co-ordinated spasm originating in the centre of speech.

Symptomatology.—The symptoms of katatonia are essentially somewhat variable in nature. There is a tendency to change from phase to phase, often returning to a previous one as if by a sort of relapse. The earliest symptoms noticed are abnormal sensations in the head, pain in the occipital region, vertigo, insomnia, irritability, change of temper, general restlessness, a certain amount of gradually increasing melancholia.

The second stage may be ushered in with convulsions, epileptic or epileptiform in character, or the patient may become suddenly maniacal or greatly agitated. The patient now presents the marked condition of melancholia. Muscular tension or spasmodic movements are present. It has been said that in about fifty per cent. of cases there are spasmodic conditions of the most varied nature, often existing for years before the beginning of the actual mental disease (hysteria [?]). Rhythmical movements about the face and limbs are often seen in this and subsequent periods. These rhythmical motions or movements are always under the control of the will, thereby differing from those seen in chorea. The reflexes are increased. The delusions are usually of fear or self-accusation, and may concern the commission of imaginary sins, masturbation, etc. Auditory and visual hallucinations of the most terrifying character are often present. Sometimes there is a condition of religious ecstasy or excitement, suddenly or gradually developed. The patient may have confused but expansive ideas of a religious or social order, and he may be given to elocutionary displays with much gesticulation. There is sometimes a tendency to talk and act theatrically. The patient is given to making pompous harangues, consisting of but fragments of sentences. There is a verbigeration or a repetition of unintelligible words or syllable successions not belonging to any language, with an especial tendency to rhyming. These are often spoken with much effort, emphasis, and forcibleness. There is a tendency to contradict, oppose, and resist everything, to refuse food, resist being washed, dressed, etc. There are a peculiar erectness of carriage, slowness of movements, and immobility of features, a pathos of expression in speaking and writing, and a tendency sometimes to mystical language, together with the effort to discover mysterious allusions in the sayings of others. The characteristic katatonic condition of tension in psychical and muscular spheres may be observed in any stage, but it may be said here that the division into stages as attempted by some authors is not altogether practical or practicable.

In the so-called attonita stage there are rigidity and immobility, which is more or less complete. Catalepsy is often extreme. There is an absence of spontaneous movements, but when we attempt to produce passive movement there is a powerful resistance. The muscles are generally in a state of tension. Opisthotonos or tonic spasms are sometimes present. The tendon reflexes are often greatly exaggerated. There is a tendency for the limbs to remain for some time in the position given them, thus forcing the patient into uncomfortable positions, as in the condition of "flexibilitas cerea." The head may be just raised above the pillow, the thighs flexed on the abdomen, and the legs on the thighs. This immobility is often interrupted by rhythmic monotonous movements incessantly repeated in an automatic manner. These stereotyped movements are called "Bewegungsstereotypie." Another very important symptom is "mutism" or "mutacismus," or a pathological tendency to be silent. This mutism or dumbness alternates often with verbigeration and other varieties of repetition. Constipation is frequently present, and occasionally retention of urine. The faradic irritability is, as a rule, normal; the galvanic is at times often diminished. "Stadia, with obstinate taciturnity, confusion of thought and speech, may occur in some cases." Dementia supervenes only slowly, and rarely becomes extreme. Dr. Julius Mickle has this to say of the grouping of symptoms: The order in which stages occur is irregular. The circular nature of the disease is extremely irregular or abortive. One or any of the stages is apt to be absent in a given case. There may be alternately:

A.—Stuporous-cataleptic phases and excited phases.

Or,

B.—Depressed and excited.

Or,

C.—Successively { Melancholic depressed. / Stuporous. / Excited. / Confused. / Depressed.

Or,

D.—Convulsive phase followed by apparent temporary recovery, then successively,

Depressed and excited phases } in series.
Depressed and hallucinatory phases }

The most frequent complication, whether preceding or following upon the appearance of the mental disease, is tuberculosis. The tendency, if recovery does not take place, is for the patient to drift into a condition of dementia or for phthisis pulmonalis to develop and carry the patient off.

There are many abortive forms of katatonia, which might be termed *formes frustes*, and it is in atypical cases, which are so often similar to other varieties of psychosis, that diagnosis is difficult. For our part we do not believe that all of the cases which have been recorded in literature are cases of katatonia in the strictest sense.

Katatonia has been divided into two forms—katatonia mitis and katatonia protracta (Neisser). With katatonia mitis there is probably simple cerebral anæmia or œdema, and with the disappearance of the œdema and a general constitutional improvement the katatonic symptoms gradually disappear. The katatonia protracta is a meningitic form, being connected with the remains of a meningitis.

Katatonia is not a common disorder. Bondurant gives its frequency as one-half of one per cent.; Cleven-

ger, one and one-half per cent.; and Kiernan, two per cent. We ourselves are inclined to consider katatonia as an extremely rare syndrome, taking it in its strict sense. It is a symptom complex, any one of the manifestations of which is frequently to be observed in various forms of insanity, and this has doubtless led to the diagnosis of Kahlbaum's entity in cases which would often prove by more exact limitations to be quite different from the true Kahlbaum type. We report in this paper four cases, the only ones we have met with in a considerable experience in large asylums for a period of fifteen years.

Differential Diagnosis.—The katatonic state can be distinguished from hebephrenia or the insanity of pubescence, in which occasionally cataleptic conditions occur, by attention being paid to the following symptoms: The delusions of the former are intellectual, commonly depressed, and vary indefinitely; the delusions of the latter are vague and stupid. There is seldom a spasmodic element in the insanity of pubescence, and the serial phases are not present. The chief diagnostic difficulty lies, of course, in the differentiation of this syndrome from such cases of melancholia as manifest attonital or cataleptic states, but the presence at some time in the course of the katatonic type of cheerful or exalted and excited conditions, together with rhythmic gesticulations, attitudinizing, and verbigeration, would be distinctive. The flexibilitas cerea of katatonia sometimes differs from that occurring in melancholia attonita, by not coming on in sudden and brief attacks of cataleptic or ecstatic character, but by lasting for a long time (for weeks). The katatonic syndrome is differentiated from hystero-epilepsy by the different general history of the disease rather than by isolated symptoms. Chorea complicating insanity is diagnosed by the peculiar involuntary and irregular movements of the former, as distinguished from the voluntary and often rhythmical movements and gesticulations of katatonia. Furthermore, insanity with chorea is not apt to exhibit such variety of phases. Narcolepsy shows none of the mental or motor symptoms of katatonia, but consists of periodical attacks of quiet slumber.

Prognosis.—The prognosis should be guarded, as in any severe form of melancholia. Complete recovery is said to occur in only about three per cent. Recovery may follow immediately upon the stage of attonita, gradually or suddenly. Prognosis is rather more unfavorable if a state of excitement follows upon the attonita. This excitement may be interrupted by a new stage of depression. It may remit and the patient appear nearly well, but generally ends in dementia. If there is to be an unfavorable termination, periods of excitement and stupidity recur with increased frequency. Three-fourths of the fatal cases are said to die from tuberculous disease. It may be here said that Kahlbaum himself was inclined to look upon the prognosis as favorable, which is rather inconsistent with his idea of an organic basis for katatonia.

Treatment.—Treatment consists in the main of following the indications common to melancholia, in paying attention to symptoms, administering tonics, sedatives, and stimulants when needed. Faradization of the chest muscles has been recommended as a prophylactic against tuberculosis, though we confess to little faith in its value. Constipation should be combated by the administration of laxatives. It is often necessary to resort to artificial alimentation when the patient refuses food. Occasionally, though, the patient will eat small portions of food when he is alone. Retention of urine is occasionally present and may require attention. Amyl nitrite is useful in cataleptic and stuporous phases. Hydrotherapy is valuable as a general tonic and stimulant. Naturally the moral treatment followed in institutions for the insane is of the greatest service. Intestinal antisepsis and the opium treatment will be found valuable in this, as in other forms of melancholia.

As an appendix to this article we publish four cases that have come under our observation, together with our comments and conclusions:

Illustrative Cases. Case I. E. K —, female, aged thirty-one; married, with four children; Hebrew; common education; born in the United States; admitted to the Hudson River State Hospital in February, 1884; no heredity. The first evidence of mental disturbance was in August, 1883, after the birth of her last child, which she nursed for two months, when she became sleepless, restless, and inclined to refuse food. Soon she developed the idea that she would never recover, began to bemoan her condition, and said it was hard to die so young. There was complete anorexia. She took no interest in anything, became careless of her person and dress, and negligent of everything in which she had formerly been interested. Three weeks before admission she became suicidal, spoke of it, and attempted to choke herself and to cut herself with glass. She would bite her caretakers, and took every means possible to make away with herself. Her menstruation was regular. There was considerable constipation. The case was regarded as one of puerperal melancholia.

February 11th, two days after admission, she tried to beat her head against the bedstead; said some one was killing her children and putting them in a box; said arsenic was put in her coffee and that her mother was in the asylum; was sleepless and had to be fed forcibly. She became rapidly worse during the next few days, went into a condition of noisy excitement, calling for her mother, whom she believed to be in the building, mentioned her delusions of poisoning, beat and bruised herself against the bedstead, and refused all food. She was very suicidal. Her mouth and tongue became dry, she showed symptoms of exhaustion, and was fed with the tube for a considerable period.

She continued to refuse food, to resist all care strenuously, and to be desperately suicidal until March 15th, when she became cataleptic with marked flexibilitas cerea, absolutely silent, noticing nothing, not even her husband, who visited her; would swallow food put in her mouth; made no voluntary motions; pulse good, bowels moved by enemata; she began to wet and soil the bed, and as she grew stronger was looked upon as rapidly becoming demented. This state of catalepsy continued, with variations from time to time, for a month or more, when she began to be destructive of her clothing, would strip herself naked, and was filthy in her habits.

She remained in that condition, seldom uttering a word for months, until about the last of November, 1884, when she began to cry out loudly, "Bring me home to my children in New York," "Bring me home to my children in New York," reiterating this over and over from morning till night, and accompanying the phrase with rhythmic movements of the hands and arms, as if she were waving them in the direction she wished to go. There was a rhythm in the days, too, for every alternate day she was quiet in her chair and would whisper. This continued without variation for some two months, during all of which time she was eating and sleeping well and gaining in flesh.

About the middle of January, 1885, her verbigeration took another character, the gesticulations remaining the same. She began to recite all day long, every other day, with great rapidity and with infinite variation in rhymes of unintelligible words as follows: "Moccasins," "voccasins," "doccasins," "crockasins," "lockasins," "tockasins," "jockasins," "hockasins," "babies," "tabies," "gabies," "habies," "sa-

bies," "labies," "mabies," "kabies," "nobis," "gobis," "jobis," "chobis," "sobis," "pobis," "tikater," "fikater," "sikater," "likater," "mikater," and so on, *ad infinitum*. She changed to another word only when the possibilities of rhyme were exhausted. She was mentally confused. When asked why she made these rhymes, she said some one told her to, but this was probably an answer given because she could not explain why, for she had now no hallucinations or delusions. She was so confused that she did not feel sure it was her husband who came to see her.

A few months later she gave up the rhyming assonances and returned to the old phrase, with occasional variations: "I want to go home to my children in New York," "Won't I be glad when I get home to my children in New York," "What good times I'll have when I get home to my children in New York, . . . to my cozy home in New York, . . . when I get into the car which takes me to my husband and children in New York." This was the refrain for many months on alternate days, accompanied as before by rhythmic gestures of both arms in the supposed direction of New York.

In the spring of 1886, on the quiet alternate days, she began to sew. She steadily improved in flesh and was looked upon as in a state of dementia. There was no appreciable change in her condition during the summer. The verbigeration and gesticulation alternated with quiet and industrious days until the autumn of 1886, when improvement began to manifest itself in every way, and in November she was discharged as improved and went home with her husband on trial. There she recovered perfectly, so that not a vestige of the insanity remains, and she is to this day in full charge of her household and family, as reported to us not long since by her husband.

In this case we have, first, an ordinary suicidal melancholia, with delusions of poisoning, the killing of her children, etc., and hallucinations of taste and hearing and possibly of sight, rapidly becoming an aggravated case of melancholia agitata (of almost maniacal character), with a sudden lapse into a cataleptic condition lasting about a month; after which she was for some months silent, stupid, having to be dressed, undressed, and cared for in every way, when she began to show symptoms of verbigeration and rhythmic gestures described above. During most of the long period presenting these symptoms she was mentally confused, but her mood was rather cheerful. She used often to smile when any one would ask her why she talked in that way, and she seemed to take pleasure in what she was constantly reiterating.

Case II.—M. S. E——, male; admitted to Hudson River State Hospital, July 21, 1891; single, aged fifty, merchant, native of New York; common-school education; habits temperate; heredity, insane relations on father's side. On admission physical condition feeble; alleged cause of insanity, ill health.

History: Patient said to have been naturally of a cheerful disposition, easily influenced, but up to fifteen years ago to have been successful in business. At this time a change took place in his disposition; he became worrisome and fretful, hypochondriacal, neglected his business, and was generally depressed. Ten months ago he gave up all work, said that he "could not walk, could not talk, or care for" himself. He became silent, melancholy, and preoccupied. Three weeks ago he became greatly agitated and confused, and since then has paid no attention to anything said to him, and has not spoken except to repeat constantly meaningless syllable combinations, like "Oh, warmee," "Oh, warmee," "Oh, warmee," "Oh, huminum," "Oh, huminum," "Oh, huminum," "Oh, wow wow woro," "Oh, wow wow woro," "Oh, wody wody wody," "Oh, wody wody wody," "Oh, wody wody wody," "Oh, kody body," "Oh, kody body," "Oh, kody body," "Oh, kody body," "Oh, widdy widdy," "Oh, widdy widdy," "Oh, hum yank-um," "Oh, hum yank-um," "Oh, hum yank-um." He would constantly repeat these words with greater or less rapidity in varying keys and with strange gesticulations and great earnestness of manner, for fifteen or twenty minutes, when he would be silent for some hours and then start off with another combination. When spoken to he would become irritable, and commence repeating some syllable combination. His appetite has been capricious. His face, head, and neck at times are much congested, and at other times he is very pale.

On admission he was much agitated, moaned, and wrung his hands, but refused to say anything intelligible; when spoken to he would only repeat the above meaningless jargon, with gestures. Bowels are constipated, tongue is coated, pupils are dilated, heart's action is weak.

July 22, 1891, restless last night, moans constantly; pays no attention to what is said to him, but repeats his combinations, as "Oh, body body," "Oh, yum yank-um," etc., and with increased rapidity when an attempt is made to interrupt him.

July 23, 1891, is in bed all the time in semicataleptic condition, lies in awkward positions, resists all care: bowels constipated, but would not submit to enema.

August 14, 1891, no special change in past month. In bed; keeps legs and thighs flexed; resists all care; never pays attention to any one; is always silent except when repeating his meaningless syllables, like "Oh, te it," etc. Bowels are obstinately constipated; frequently troubled with emesis; is cared for with difficulty on account of his persistent resistance; often moans and groans, often has rhythmical movements of upper extremities.

During August, September, October, and November there was but little change in his condition.

In December he became stronger physically; was less resistive to care, would dress and undress himself; appeared to understand what was said to him, but never made any intelligible replies, but would frequently make harangues in meaningless syllables, repeating one combination from twenty minutes to one-half hour, and then changing to another.

January 27, 1892, spoke to-day intelligibly for the first time since admission; said to the attendant who was about to take him out to walk, "Don't let them take me out to-day."

January 28, 1892, is again disturbed and excited. Verbigeration marked.

During February and up to the 25th of March he was much disturbed, often noisy for hours at a time. An almost persistent insomnia was present. The latter part of February chronic diarrhœa developed, and persisted in spite of treatment.

March 25, 1892, he again spoke coherently and his verbigeration now stopped. Is very depressed and resists care. Has become thin in flesh and is quite feeble physically; is in condition of attonita; muscles in condition of tension; resists every change of position.

April 7, 1892, has been quiet since last date, but has resisted taking food and all care most strenuously; has had chronic diarrhœa and has been steadily failing for some weeks. Died this morning.

Post-mortem refused by friends.

Case III.—W. J——, admitted to Hudson River State Hospital, November 17, 1894; aged forty-four, male, married, railroad employee, native of Ireland; common-school education, habits intemperate, heredity denied. Physical condition on admission, fair; alleged causes, intemperance and worry and anxiety on account of loss of position.

History: Six months prior to admission patient lost his position on the railroad, and was unable to obtain work, and he and his family suffered much privation in consequence; he worried much at not being able to obtain employment, and gradually became depressed and despondent, and about four months ago attempted suicide by cutting his throat. The wound healed, but he became more and more despondent and suffered much anxiety at not getting work; is now troubled with insomnia and headache. A few days ago he suddenly went into a condition of extreme excitement, broke his watch, upset the table, and was generally destructive and violent. He was taken to the lockup for care. This condition lasted about three days, when he became quiet and appreciated his condition.

On admission he was profoundly depressed and indifferent to his surroundings; answered questions coherently but very unwillingly. After being here two days he went into a condition of melancholia agitata, which lasted two days; he suddenly became stupid, confused, and was in a condition of semicatalepsy, refused to talk or to speak. After being this way for two days he again became greatly disturbed, and continued so for five days. During this time he resisted all care, seemed utterly indifferent to his surroundings, at times was noisy, strenuously resisted all care and taking food, and it became necessary to nourish him through the œsophageal tube. He now became quiet, but continued to refuse food and was fed through the tube nearly two months. He had delusions of poisoning and would rarely answer questions, but would frequently groan and moan.

On February 13, 1895, he had two very severe epileptiform convulsions. During February and March he refused food, often moaned and sighed, but had no conversation with any person and resisted strenuously all efforts at care. During April and May mutism was marked, patient lay quietly in bed and did not speak a word, resisted care, kept lower limbs flexed and eyes shut half of the time: muscles were in a state of tension.

On June 10th verbigeration appeared. He kept repeating for hours, "O Lord, what will I do?" "O Lord, what will I do?" "O Lord, what will I do?" but otherwise was mute and paid no attention to any one or to his surroundings, but always resisted most strenuously being changed, cared for, or interfered with in any way. This condition continued with but little variation for six months. During this time he was visited repeatedly by his wife and family, but at no time did he pay any attention to them or hold any communication with them. He was continually in a state of attonita, but would often groan and moan, and at times would repeat for half an hour or an hour at a time, "O my God, what will I do?" "O my God, what will I do?" "O my God, what will I do?" with automatic gestures.

The latter part of 1895 he developed phthisis pulmonalis. He was in bed almost continuously during 1896, and his condition was that of attonita generally. His muscles were usually rigid and in a state of tension, his lower extremities flexed on the abdomen, and the face on his chest, his lips pouting out, his eyes usually half-closed, paying no attention to any one, but always making the most strenuous and persistent resistance to all efforts of care. He would daily have periods, of varying duration, of repeating in varying tones of voice sentences such as, "What will I do?" "What will I do?" "What will I do?" "O my God!" "O my God!" "O my God!" "Lord, have mercy on me!" "Lord, have mercy on me!" "Lord, have mercy on me!" etc. These repetition sentences varied from time to time.

He is now, in April, 1897, in the last stages of phthisis pulmonalis. He occasionally has verbigeration, but only once in three or four days. He is almost constantly in a stuporous condition. With the exception of his periods of repetition of words and sentences, he has been mute for more than two years and has held no communication with anybody. He is much emaciated and is steadily and slowly failing.

Died May 5, 1897.

Case IV.—D. M——, admitted to Hudson River State Hospital, May 26, 1896; male, married, aged fifty-four, railroad employee, native of Ireland; common-school education; habits intemperate; heredity denied. On admission physical condition feeble. Alleged causes of insanity, intemperance and ill health.

Patient enjoyed fair physical health up to about twenty months ago, when on returning from his work he complained of being sick and went to bed for a few days, and ever since then he has been more or less depressed and troubled with insomnia. He would often moan and groan all night, frequently wringing his hands. He, however, worked in an automatic manner up to two months ago, but he took no interest in anything, and on returning home in the evening he would moan and pace the floor until two o'clock in the morning, when he would lie down on a lounge for three or four hours. He was very hypochondriacal and restless; thought that everything he did and every move he made were wrong. His condition gradually became worse. At present he cannot sleep or rest day or night, paces the floor until his feet are blistered, rubs his forehead and wrings his hands until they bleed; refuses to go out of doors; says that he is miserable and wants to die, that there is no hope for him. After several hours of excited hand-wringing and pacing up and down, he becomes more composed and says to his wife, "What a bad spell I have had." He has had severe occipital headaches for the past two years, often sees black specks floating in front of him, and is troubled much with hearing imaginary voices and noises. Has numerous delusions of a depressing nature, is very self-accusatory, says that he has committed a mortal sin by practising masturbation, and that he must die.

During the first three days in the hospital he was quiet, depressed, reticent; eyes had a furtive, shifting appearance; said he was in great mental trouble; had periods of walking the floor and rubbing and wringing his hands in a strange manner.

May 29, 1896, had a convulsive attack this afternoon; afterward was very confused and was put to bed. He now became much disturbed, moaned and groaned a great deal, was very emotional, often cried and wept, had periods of picking the bedclothes, lay in one position, and resisted being changed and cared for.

This condition continued until August, when he began having periods, lasting for some hours, of being in a cataleptic condition. At all times he was depressed, but would often talk and declaim, with gestures, about the money he had made and how successful he had been at times. No special change occurred in his condition during September and October. The fore part of November he became very confused, and the symptoms of verbigeration occurred now. He would sit or stand and repeat, with monotonous and continued gesticulations, "I want to go home," "I want to go home," "I want to go home." . . . "I want to go home," "I want to go home," "I want to go home," etc.

During November and December verbigeration was very marked. He would frequently repeat, "I beg your pardon," "I beg your pardon," "I want to go home," "I want to go home," etc.

During January he was confused and quiet. Verbigeration was less frequent. In the fore part of Febru-

ary verbigeration again appeared, and often for hours he would repeat, "I am wrong," "I am wrong," "I want to go home," "I want to go home," "I do," "I do," etc., with monotonous gestures. This condition continued during February and March. These periods of noisy excitement would alternate with conditions of comparative quietude, when he would be in a semi-cataleptic condition.

In April his excitement increased, and he frequently, while making his harangues, would pull or tear his ears in addition to his other gestures. Often he repeated, "I know it," "I know it," "Kill me," "Kill me," "I should not be this way," "I should not be this way," "Why should I be so filthy?" "Why should I be so filthy?" He often seemed to be in great fear.

The patient is still under observation and is becoming very thin in flesh; often resists care; is very emotional, and has periods of noisy verbigeration alternating with comparative quiet.

Observations.—If there is one feature which impresses itself strongly upon the mind in reading the histories of the four cases just described, it is that of the melancholia present in each and characteristic in every respect of common types of this form of insanity. The cataleptic and allied motor phenomena observed in katatonia are not infrequently observed in severe forms of melancholia, in which the terrible nature of the ideas seems to exercise a paralyzing influence over the whole motor mechanism, but the physiology of these symptoms is not yet understood. As cataleptic conditions are often noted in insanity associated with hysteria, in pubescent insanity, in epileptic insanity, sometimes in general paresis, and in hypnotic states, they cannot be regarded as constituting a distinctive feature of katatonia. The most important characteristic of the katatonic syndrome serving to distinguish it from melancholia with catalepsy would seem to lie in the verbigeration and rhythmic gesticulations. But even these symptoms are met with in other forms of insanity, and the automatic repetitions of set phrases with automatic, even rhythmical movements, though not so marked as in these extreme forms to which the name katatonia has been applied, are familiar enough phenomena in long-continued cases of ordinary melancholia.

Conclusions.—Our study of the subject and of our own cases leads us to the following conclusions:

1. Katatonia is not a distinct form of insanity, not a clinical entity.

2. There is no true cyclical character in its manifestations; hence it cannot properly be classed as a form of circular insanity.

3. It is simply a type of melancholia.

4. It is not desirable, therefore, to retain the name katatonia.

5. The term "katatonic melancholia" or "katatonic syndrome" may be usefully retained as descriptive of melancholia with cataleptic symptoms, verbigeration, and rhythmical movements, but should be strictly limited to this symptom complex.

6. The prognosis in melancholia with katatonic symptoms is more grave than in any other form.

7. The treatment of the katatonic syndrome is the same as for other types of melancholia.

A CASE OF ACQUIRED ATRESIA OF THE VAGINA, COMPLICATED BY PREGNANCY.[1]

BY AUGUSTA VELDEN, M.D.,

M. C——, Italian, aged thirty-five years, came to the dispensary September 10, 1896, on account of suppression of the menses for six months. She had been married fifteen years, had given birth to one child fourteen years ago, and since had menstruated regularly until six months ago. On my suggesting an examination for pregnancy, she said that this was impossible, and explained that the vagina had been "closed up" for fourteen years. Examination showed this to be really the case. The vagina ended blindly at the junction of the lower and middle third or about one inch from the introitus, being constricted in a funnel-shaped manner by a very dense cicatricial ring, the apex consisting of a small diaphragm of very firm unyielding tissue, which seemed completely imperforate, but on close inspection through a speculum showed a minute opening, which admitted on pressure a fine probe, and through this the menstrual flux had escaped *guttatim* during all these years. The parts were sensitive to pressure. The vulva gaped somewhat, on account of the perineum having been lacerated, and presented a rectocele and cystocele below the cicatricial occlusion, making the stenosis appear nearer the vulvar orifice than it really was. Above the symphysis was a globular, elastic tumor, which could not very well be anything but the pregnant uterus of about four months.

The history of the case was as follows: The patient became pregnant for the first time fifteen years ago, with the result of a stillbirth at term, after a protracted labor superintended by a midwife. She states that the head descended into the soft parts of the pelvis, and, remaining there, made no further progress. The parts became œdematous and very painful and "turned black," but the midwife did not consider it necessary to call a physician. Finally a dead child was born without any operative interference, the labor having lasted twenty-four hours. She states that after this she was very ill and had fever, but cannot give any further intelligent account of the puerperium; twenty-two days after delivery she discovered that the vagina was completely occluded, and sought the advice of a physician in Palermo, who recommended operation. This she refused, and the condition that existed then had now existed for fourteen years, with this variation only, that a pregnancy had now supervened. There is no doubt that the atresia in this case was due to the prolonged pressure of the head on the vaginal walls, thereby causing necrosis and extensive loss of tissue, resulting in the formation of cicatricial tissue. The patient had in no way been aware of any narrowing of the vagina previous to her accouchement.

Being informed of her condition, and told that an operation was necessary, she consented, although incredulous as to her pregnancy. Five days later she was etherized; the pin-hole opening was incised until the finger could be admitted, which revealed the fact that the very dense annular stricture was about one-half inch in thickness, thinning out toward the lumen. Above, the vagina was ample, and a softened cervix was felt and bimanually the pregnant uterus of about four months. With the galvano-cautery knife the thick cicatricial tissue was cut through in several places—care being taken to avoid the urethra and rectum—until a large Cusco speculum could be introduced and opened widely. A thick plug of iodoform gauze was placed in the vagina and renewed daily after antiseptic douches, until the vagina was healed and promised well to remain in a good condition. But it was soon evident that contraction was beginning again, in spite of the tamponing. The patient ceased coming regularly to the clinic which she had attended after the vagina was sufficiently healed, and when she returned after a time of absence it was found so contracted that it with difficulty admitted the index finger, and attempts at dilatation were of no avail. The pregnancy was advancing, and the patient herself was now becoming convinced of her condition. It was then decided to wait for a time to see if any spontaneous softening would take place, but such not having been the case in the course of three months, it was decided to open the vagina again and introduce a large Sims glass plug. It seemed reasonable to think that whatever ground could be gained before the advent of labor would be an advantage, obviating the dependence on incisions and forceps *sub partu*, with incalculable rents and surely a field for infection.

On December 20th the patient was etherized again, being at this time nearly seven and a half months pregnant. The stricture now just admitted the extreme tip of the little finger. The galvano-cautery knife was again used, as it seemed on the whole preferable to avoid hemorrhage in a pregnant woman already anæmic, and also it seemed that a large glass plug ought to overcome effectually the greater tendency to cicatrization and further solidification consequent on using the cautery. Several incisions were made around the entire circumference of the cicatricial mass, avoiding urethra and rectum, laterally cutting more deeply than the previous time, to secure as much space as possible. Judging from the not inconsiderable bleeding as it was, it must have been excessive had a bistoury been used. A Sims glass plug, four and three-fourths inches in circumference, the largest that could be secured then, was introduced and held in place by a stem inserted into the hollow of the tube (in this case the large vaginal nozzle of a fountain syringe) with four bands attached, the latter being fastened to a waistband. Cotton was packed around the stem in the hollow of the tube, and, planted firmly in this way in the cotton, it proved an effectual means of keeping the tube in place. There were no untoward effects from the operation. Two days later a slightly larger glass tube was secured and introduced before any contraction had taken place. After a few days digital examination showed the vagina healed and spacious without any vestige of the constricting ridge, the mucous membrane being uniformly smooth and relaxed. The glass plug was now exchanged for a Sims plug of hard rubber, to avoid the danger of breaking; this latter measured five and one-fourth inches in circumference, and was thought to be as large as the patient could wear without too great inconvenience. To prevent irritation, cotton was padded about the vulva under the flanges of the tube and under the bands. It was removed daily for cleansing and irrigation of the vagina, being worn otherwise constantly and without much discomfort. But on the fourteenth day after the operation the patient allowed the tube to come out, and, having left it out for sixteen hours, was unable to replace it. I found the vaginal lumen contracted and could not replace either the tube worn daily or the next smaller size, and, having no other with me, the patient had to spend the night without a tube.

The following morning, January 3d, I found to my chagrin that the only tube that could be introduced was the fourth in order of size from the one worn daily, being one inch smaller; the constrictor vaginæ resisted as firmly as if already transformed into a cicatricial band. January 4th, I found the vagina

[1] Read before the Alumni Association of the Woman's Medical College of the New York Infirmary, March 12, 1897.

more relaxed, the constrictor vaginæ having been partially paralyzed by the tube, so that the next larger could be inserted with ease. January 5th, I replaced the tube by one next larger, without difficulty. In this way having gradually returned to the largest hard-rubber tube this was worn up to the commencement of labor, except for daily irrigation of the vagina, the patient continuing in a good condition throughout.

Thus the calibre gained, five and one-fourth inches, was maintained up to the very beginning of labor, but as for any further spontaneous softening or increased dilatability as the pregnancy advanced, none could be detected. The vagina continued to feel spacious, no constriction or ridge being discoverable by the examining finger, but through a large glass tube one could see a pale zone of tissue, the path of the former stricture, half an inch wide and surrounding the entire vagina, and attempts to stretch this with two fingers showed it to be unyielding. The introitus vaginæ and adjacent parts also showed a noticeable lack of softening, and the varicose condition and consequent violaceous or purple hue common in advanced pregnancy was almost absent.

Labor pains commenced on February 12th at midnight (at term, having been predicted for February 10th), becoming frequent and violent at 7 A.M. While the cervix was dilating, which it did but slowly—the amniotic fluid having escaped gradually during the last three days—the condition below did not seem unpromising, except for a slight bridge of tissue in the right upper quadrant of the vagina, the only part of the zone formerly a stricture that in any way suggested a stricture, and had it not been for previous knowledge of the condition of the vagina one would not have thought of any abnormality or noticed any barrier to delivery, except for the slight ridge just mentioned, which was elected as a site for incision should such be needed. The recto-vaginal septum was smooth, relaxed, and thin, and there surely no incisions could be made. But no sooner had the head passed the cervix than it became too evident that the zone of new tissue was a most formidable barrier to the further progress of the head. The channel of five and one-fourth inches that had been attained through the operation was of no more yielding nature than the pin-hole opening first discovered, and formed a hard circle on which the violent pains had no effect whatever. Instead of dilating, the aperture seemed to become actually smaller, with the head pressing hopelessly against it. This opinion was concurred in by Dr. Frances Young and four students who witnessed the case with me, who an hour before had been unable to discover any signs of a stricture and now like myself became convinced of the unyielding nature of this new tissue. After a period of terrific pains and no yielding, two incisions were made with a probe-pointed bistoury introduced between the head and the vaginal ring, in the right upper quadrant, one rather superficial, one deeper, causing considerable hemorrhage but no apparent progress. The incisions were made during the pains, and the patient felt then comparatively little on account of the severity of these. Half an hour later, nothing having been gained, two more and rather deeper incisions were made, one in the left upper quadrant of the circle, the other laterally on the left side, with profuse hemorrhage, which, however, was soon checked by the on-pressing head. The violent expulsive pains were now effectual, and in a few moments the child was delivered, slightly cyanosed but soon revived. The placenta followed immediately and the uterus contracted well. The child was followed by a gush of meconium and had meconium in the mouth. The labor had lasted in all ten hours, with severe pains the last three hours. The patient was in a good condition and had felt the incisions only slightly, except the last one. On examining the vagina it was found that the incisions had enlarged into considerable rents, which, however, had not extended into dangerous ground. The last deep cut proved to be rather closer to the vicinity of the rectum than was intended, but there was no tear into the rectum. The deep incision on the right side made a pocket-like rent upward in the vagina. The thinned, now bell-shaped cervix was well constricted at the internal os and the vaginal roof all around the cervix was intact, no tear having reached up to that vicinity. The cervix was prolapsed so that it partly protruded at the vulva. There was very moderate hemorrhage after delivery. The vagina was syringed out with warm carbolized water. It was thought best to leave the wounds unsutured, as it seemed that the lochia flowing over them would delay their healing and thus prevent contraction to some extent.

The infant was of the male sex, weighed seven pounds, and was to all appearance healthy. It presented the anomaly of a supernumerary toe on the right foot.

The puerperium was uneventful and recovery uninterrupted. The vagina was irrigated daily with sterilized water. There was at no time any rise of temperature. On the eighth day, the vaginal wounds being healed and no longer tender, a vaginal speculum was introduced with instructions to wear it two or three hours daily if possible, which was done for some days.

In searching through the literature for information while observing this case, it was found that of 313 cases of atresia vaginæ complicated by pregnancy—299 of which are collected by Neugebauer[1]—257 were delivered *per vias naturales*, while 56 required Cæsarean section. Of the 257, spontaneous delivery occurred in 82 cases, the majority of these being of the membranous or congenital variety, or simply narrowings of the vagina, 11, however, resulting fatally from rupture of the uterus or vagina or from peritonitis. In 122 cases delivery was accomplished by incisions or by forceps, or by both, with 18 deaths from rupture of uterus or vagina, peritonitis, and eclampsia. In 21 cases version, perforation, or embryotomy was required, 6 ending fatally for the mother, the death rate for the child being in all the cases, by whatever mode of delivery, naturally much larger. The remaining cases, 32 in number, are incompletely described. Of the 56 cases that required Cæsarean section, several had contracted pelvis in addition to the atresia.

Of operative measures during pregnancy on account of atresia vaginæ, eight cases have been gleaned—one of artificial abortion in the fifth month,[2] two of artificial abortion in the seventh month, one with perforation of the head (159 and 233);[3] one of operation for a membranous stricture (293); one case operated by Behn (62), in which incisions had to be made during labor nevertheless; one (98) in which stricture returned, *subpartu* incisions and forceps, eclampsia and death; one (254) in which the lumen of the vagina was enlarged sufficiently to admit two fingers, by means of two longitudinal incisions laterally, one of which was sutured transversely, the other covered by a bit of tissue from a colporrhaphy case just operated upon—later, contraction so that one finger only was admitted, *subpartu* incisions and forceps; one[4] of operation in the third month for congenital absence of vagina with enlarged meatus urinarius, aborting on third day.

As regards the post-partum return of the stricture, mention is made in only ten of the cases, in nine of

which there was almost complete return, in one no return in five weeks. In the present case the vagina is as yet ample, four weeks after delivery.

THE EARLY DIAGNOSIS OF SPORADIC CRETINISM, WITH A REPORT OF TWO CASES OF CONGENITAL SPORADIC CRETINISM.

BY HENRY KOPLIK, M.D.

INFANTS or children who are the subjects of sporadic cretinism, in whom the disease has existed for a year or more before the diagnosis is made and treatment with thyroids begun, are not always restored to a mental and physical state exactly equivalent to the normal one. The writer has observed in two cases which have come under his observation that although the symptoms of idiocy and myxœdema disappeared, the children after fully two years of treatment remained somewhat deficient in physical and mental development. In one case, a boy, fifteen months old when treatment was begun, after two years of constant administration of thyroids, is still unable to talk sentences. The vocabulary seems limited to a few words of one or two syllables. The physical development is that of a child a year or so younger. In another case, in which the treatment was begun after the disease had existed fully a year or more, the child, though bright, talks to a very limited extent.

If these things are to be confirmed by other observers, as I am certain they will be, it would seem highly desirable to recognize this disease very early in its development, before the nervous system has been seriously compromised by a more or less prolonged period of retarded growth or action of infectious agents or influences which are active in this affection. In the published American literature of sporadic cretinism, we have no cases of congenital cretinism (sporadic) published as such. Townsend,[1] in 1894, reported a case of congenital rickets which terminated fatally in nine days. If we accept the classification of Horsley, we should now include this case as one of congenital sporadic cretinism. Of the cases published by foreign authors, we find that only a mention of the congenital cases is made by Fletcher Beach,[2] who in a study of fifty-two cases of sporadic cretinism found only nine cases which showed symptoms at periods from birth up to the ninth month. There is reason to believe that a vast number of the cases published, especially those cases which have come under treatment at the age of one and one-half years to two years, forming the mass of the literature in America, must have been sufferers from the disease long before the symptoms were discovered by the physician. In many of the younger cases of sporadic cretinism the history will state that the mother first noted the illness of the infant at the fifth or sixth or twelfth month. These statements are fully unreliable. It will be seen that in the two rare cases here reported by the writer, the mothers did not notice anything wrong with the general condition of the patients and came for relief in other directions (intestinal colic or jaundice). In one case a physician failed to notice the symptoms which were characteristic of beginning cretinism. The children or infants who are as a rule brought for treatment to the clinics, and who are suffering from sporadic cretinism, are brought at a period when all the symptoms have developed in their most pronounced types, so pronounced and marked that not only the mothers but strangers are cognizant that the patient is well started on a form of severe disease. It is for these reasons and to aid the early discovery of the cases of this disease, that the following rare examples of early cretinism are published as a distinct set of cases.

FIG. 1.—Congenital Sporadic Cretinism, before Treatment. Child four weeks old. (Case I.)

FIG. 2.—Congenital Sporadic Cretinism. Child shown in Fig. 1, after four months of treatment.

CASE I.—Female infant, aged one month, seen first December 24, 1896. This infant is a sister to a fully developed cretin, and is the first infant born to the mother after the cretin referred to had been under treatment fully two years. Mother and father are first cousins; no goitre in either. The birth was a normal one. When the child was four days old icterus neonatorum appeared and persisted six weeks. At the age of one month, the mother brought the infant to me for jaundice. I saw a fairly nourished infant still jaundiced; the expression of the face was strikingly prognathous. The infant did not cry unless severely teased; it seemed very torpid. The head was broad at the base of the skull, smaller at the summit, not markedly pointed. The abdomen was distinctly rotund. The extremities were short, but not deformed. The child was short and thick set. There was no myxœdema of the skin, but the whole surface was cool to the touch; the lips were slightly puffed; the tongue was very large and thick (macroglossia); the neck was short and thick.

Head: circumference, 38 cm.; antero-posteriorly, 23 cm.; bitemporal, 20 cm.; rather of the oxycephalic type.

Fontanelle, anterior, 3½ by 2 cm.; sagittal suture open to the occipital depression

Thyroid gland not palpable.

Hæmoglobin, 85.

Temperature, rectum, 96° F.

As said above, the child was stupid, and clapping of the hands failed to attract its attention. Under thyroid treatment the temperature gradually rose in the rectum to 98° F. The infant became bright and seemed to notice surroundings, and smiled. The tongue became markedly thinner and the face normal in expression. It played and laughed and cried as other infants; the forehead was broader and had lost its wrinkled appearance.

February 15th, hæmoglobin, 60. Temperature, rectal, 98.4° F. At no time could the thyroid be felt and no supraclavicular masses of fat were present.

In this case we find a newborn babe, whose mother had previously given birth to a cretin, showing symptoms of slight cretinism. The stupidity of the infant, the reduced internal temperature, the peculiar con-

[1] Archives of Pediatrics.
[2] British Medical Journal, 1896.

formity of the extremities as related to the trunk, the wrinkled skin on the forehead and hands, the narrow animal forehead, the thick lips, the thick immense tongue (macroglossia), the coarse cry, the immediate improvement of the stupidity under thyroid, and the reduction of the thickened and hypertrophied tongue —all point to the inevitable conclusion that here we had to deal with a congenital cretin, who if allowed to progress would develop the symptoms of the disease in their more pronounced forms. It is an interesting fact that in this case, early in the disease, the hæmoglobin was greater than later on, though the infant was immediately placed upon thyroids. This was also the case with the second patient, in whose history blood data are given and which will be discussed later on.

May 25th, at the present day, with six months of treatment, we have a very bright and interesting infant, in every way resembling the normal infant. It attempts to stand and utters sounds. The infant is still under thyroid therapy, one-half grain t.i.d. On the whole, the infant is a much more satisfactory case after six months of treatment, as far as restoration to normal conditions is concerned, than its brother was after the same period of treatment. The brother came under my care at the age of fifteen months, at that time a fully developed cretin. He is also still under observation. Though two years under treatment, as stated above, the brother is not the complete equal of other children of his age. He cannot talk sentences: is an interesting child, but impresses one as equal to a child of two years of age rather than one nearly four years old.

Case II.—W. F——, female infant, nine weeks old. Mother and father healthy; mother or father have no goitre nor any other abnormalities; no consanguinity. This is the first baby; breast fed. Mother from birth of the baby, which was normal, head presentation, noticed that the baby was stupid. The baby did not resemble either parent, having a small low forehead, flat nose, puffy eyelids, thick lips, and large tongue. The abdomen has been quite large, and the baby cried incessantly, so much so that the mother took the baby to a physician, who diagnosed an obstruction of the gut. She then brought the infant to the writer.

Status præsens: Looking at the infant, it has the gross characteristics in expression of a typical cretin, but in less pronounced form. The forehead is low and narrow, the eyelids are puffy and œdematous in appearance, the bridge of the nose is flat, the lips are thickened: the tongue is large, broad, thick, and protruding at times. The abdomen is large, and the thighs and legs are quite dwarfish as compared with the size of the trunk. The skin has a greenish hue; no thyroid can be felt; the external temperature of the skin is much below normal, hands and feet are cool; skin of hands has a finely wrinkled look. Cry is coarse and deep. Internal rectal temperature, 97.8° F. The bowels are constipated.

Measurements, head: fontanelle, anteriorly and posteriorly, open; glabella to occiput, 18 inches; vertex, 8¼ inches; bitemporal diameter, 9 inches. Chest, 14 inches. Length of arm, 13¼ inches; length of forearm, 8½ inches. Length of body, 18 inches.

Blood, May 15th (Fleischl): Hæmoglobin, 105; red cells, 3,026,000; white cells, 13,500. April 29th, hæmoglobin, 55. May 22d, hæmoglobin, 65.

Course of case: The infant improved in its general appearance from the first week of treatment. The writer noticed that it became quieter or brighter. The puffiness of the eyelids has gradually subsided. The lips have become thinner, and the tongue has improved, so that to-day it is quite slender and much like the normal tongue. The temperature has gradually risen to the normal, and the color of the skin has lost its greenish tint and taken on a healthy hue. The cry is no longer deep and hoarse. The abdomen is not large and distended, and the dwarfish appearance of the legs has disappeared. The baby seems as bright as a normal baby of its age (three and one-half months). The expansion and growth of the forehead and bridge of the nose, both of which have lost their cretinal conformity, are most interesting, and now the face has a tolerably pleasant appearance. The baby is beginning to remember its mother. Takes thyroid, one-half grain t.i.d.

In the above case we have a typical cretin of the congenital type. There were all the symptoms of cretinism developed in an early stage. The beginning myxœdema of the skin, the prognathous expression of the face, the low forehead, the flattened bridge of the nose, the thickened eyelids, the thickened lips, the enlarged and thickened and broad tongue, the dwarfish conformity of the body extremities as compared to the length of the trunk, the protuberant abdomen, the skin of a greenish hue, the marked torpor, reduced internal

Fig. 3.—Congenital Sporadic Cretinism, before Treatment. Child ten weeks old. (Case II.)

Fig. 4.—Congenital Sporadic Cretinism. Child shown in Fig. 3, after one month of treatment.

temperature—all point inevitably to the diagnosis of congenital sporadic cretinism.

It may be remarked that the hair in this case was not as yet dry and sparse, but glossy and abundant.

The blood examinations in both these cases were of interest, showing that in the very early stages of the disease the blood is not affected by an anæmia such as we find in advanced cases which have not been the subject of treatment. Thus in an advanced case, aged fifteen months, the hæmoglobin before treatment was 18 (Fleischl); in another, aged twenty months, 25 (Fleischl). In the first case reported in this paper, the hæmoglobin fell to 60, and now is 65. In this case the hæmoglobin was taken after treatment had been begun. In the second case, hæmoglobin at the outset, 105; red cells, 3,026,000; white cells, 13,500. April 29th, hæmoglobin, 55; May 1st, hæmoglobin, 53; May 22d, hæmoglobin, 65.

Thus we have at the outset nothing otherwise than is found in the normal infant, as far as the hæmoglobin is concerned; the blood has the characteristics practically of the so-called fœtal blood of Hayem.

ROUGH NOTES ON SOME ANOMALIES IN ANATOMY.[1]

By R. HARCOURT ANDERSON, M.D.,

THE anomalous anatomical conditions, or, to use the term of the biologist, specimens coming under the title of variation, found in the dissecting-room as a rule are viewed by the average student in the light of those conditions which we are wont to designate mere scientific curiosities, or, if attention be devoted to the etiological factors in the production or evolution of the same, the subject is usually viewed in a superficial sense. The modern student of human anatomy, ever on the alert for the practical, and looking at these deviations from the normal with the eyes of the author of his text-book, little knows the fund of information to be gained by an investigation which would lead into the domain of the comparative anatomist or thinks the requisite knowledge of human anatomy to be so difficult of attainment that the time spent in the consideration of anomalies would be wasted.

There is so much drudgery of thought connected with acquirement of the almost endless details of practical anatomy that it will be admitted fair treatment to make use of any honest means to fix the composite parts of the complex subject in our minds, and so the study of anomalous conditions will be seen to be one of the pleasant byroads to our goal, although perhaps more applicable to the advanced thinker than the college student. To review this subject it is necessary that the ploughshare of thought be forced into ground which has already been deeply furrowed, but it is not the object of this short paper (which is arranged in the form of notes, more or less closely connected) to enter deeply into the very interesting but mostly theoretical disputations concerning the causation of anomalies, which necessarily include those very complex subjects, viz., evolution and heredity

It will answer our purpose to touch lightly on some of the more prominent facts and theories, recalling at this time the words of that great thinker, Darwin, that "we are extremely ignorant on this subject."

Now we may state in passing that even the least important deviations from the normal which may be found form certain or uncertain indices to the processes intimately connected with knowledge of changes that are to be considered in the study of evolution.

According to the verdict of advanced thinkers and investigators, man now takes his place in the zoölogical system, and therefore comparative anatomy is recognized as an infallible key to human anatomy. Such low forms of structure as the cranial bones of the osseous fishes, though exhibiting numerous varieties, admit of being compared with even those of the human subject; again, in the muscular system we see that the musculus psoas parvus, which is often absent in the Caucasian race (although Cruveilhier has found it even double on both sides), exists frequently although sometimes unilaterally in the negro and is invariably present on both sides in the ape. Many illustrations are possible, but so much for adult structure.

Regarding the influences of stages of embryonal development, those in the higher structural organizations bear a certain definite relation to permanent arrangements in the lower animals, viz., the intermaxillary bone, which in man is found only in the earliest fœtal period, occurs in all the mammalia and supports the incisor teeth, except when there are none. A vast number of examples can be quoted, all pointing to analogy in the growth of higher and lower organisms.

Read before the New York Medical Association.

Before the views of Charles Darwin were given to the world, most naturalists believed that species were distinctly created and immutable productions, although there were not wanting at that time observers whose words indicate the belief that species do undergo modification and that existing forms of life are descended by true generation from pre-existing forms. Even prior to this, referring to classical writers, Aristotle, in "Physical Auscultationes,"[1] foreshadows the theory of natural selection.

Lamarck in 1801 upheld the doctrine that all species, including man, are descended from other species, and that all change, in organic as well as in inorganic structures, is the result of certain laws, chance never entering into evolutionary factors. These conclusions were based on gradual change of species by difficulty in distinguishing species and varieties, by gradation of certain forms, and by production of analogical characters. He attributes something to the direct action of the physical conditions of life, something to the crossing of already existing forms, taking into consideration use and disuse, *i.e.*, habit. He held to a law of progressive development, that all forms of life thus tend to progress, and he accounts for the present existence of simple productions by the view that they are now generated spontaneously.

Geoffrey St. Hilaire, as early as 1795, suspected that what are now known as "species" are various degenerations of the same type, though he did not believe that existing species are now undergoing modification.

Dr. W. C. Wells, in his famous "Two Essays upon Dew and Single Vision," recognizes distinctly the principles of natural selection, applying it only to races of man and to certain characters alone.

Mr. Herbert Spencer concluded that species have become modified, attributing the modification to change of circumstances.

In view of the investigations made by many illustrious observers during this century in the domain of comparative anatomy, we may define an anomaly proper as the deviation at birth from what is recognized to be the ordinary structural composition and form, comprehending in the analysis various influences, such as habit, nationality, climate, heredity, the transmission of mutilations; and space is given by some observers to the retrograde change called degeneration, the influence of which on some races and individuals is abundantly shown. And here it may be admitted that some organs in man are distinctly degenerative and anomalous; for instance, his teeth are mechanically inferior to those of the domestic cat; some of his senses, suchas smell, are also lacking in acuteness; but by virtue of his massive brain and complicated hand he is the most adaptable and intelligent vertebrate on the surface of the globe.

Regarding the rôle which anomalies play in the evolution of man, at least as far as the muscular system is concerned, I will quote Osborn: "The evolution of a new type must consist in the accumulation of anomalies in a certain definite direction by heredity, and therefore an anomalous condition in one generation may become typical in another."

Galton has very aptly said that the human organization is a new building built up of fragments of old ones, the old ones corresponding to various types of life extending into the back ages; at least the evidence on this point is just as conclusive and even more so than that upon which geologists recognize the age of this terrestrial globe.

It is more reliable, inasmuch as dependence is not based altogether upon fossil characters. Such rudimentary structures as the appendix vermiformis and the musculus panniculus carnosus were undoubtedly

[1] Lib. II. cap. viii.

formerly of some specific use, functionally or otherwise, to the requirements of the economy at that time. The presence of these and other structures included as anomalies partially illustrates the conservative power of heredity.

Probably no organ is stationary in development, although apparently it would seem so under certain conditions of environment; this, however, is occasional, and physiological and biological evidence goes far toward proving that almost all organs are in a state of change, some more rapidly than others, and here it may be mentioned that man, as a whole, is in a state of evolution almost as rapid as that which has produced the modern horse from its small five-toed ancestors.

Looking into the subject practically, the difference in determining whether an organ is developing or degenerating at the same time is great; its variability or tendency to present individual anomalies indicates that some change is taking place. This is shown in the very variable peronæus tertius (Wood) and numerous other muscles, among which is the palmaris longus.

Now, as change of organ is associated with degree of utility, in the analysis we must include the amount of service rendered by the part, and, as this is often determined by the amount called upon for the maintenance of function necessary to health under various conditions of life, a few words upon the influence of habit will not be amiss.

In the production of anomalies in individuals we have as factors the destructive power of degeneration, which is essentially adaptive as against the protective power of heredity, and the result may be viewed minus or plus the influence of habit and the various conditions of life. It is collateral to this sentence that the part found to be degenerating by disuse in the individual will almost invariably be found to be degenerating in the race, illustrating again the conservative influence of heredity and also of conditions of life upon racial characteristics.

Some of the most conspicuous features of modern habit are the considerations of the fashions and occupations which demand complicated movements of the thumb and fingers, the outward turning of the foot in walking, and movements of the forearm.

Thompson concludes that the tibia is the most variable in form and length of any long bone in the body. Platycnemia or flattened tibia is most frequent in people following occupations involving climbing, etc., and is usually associated with great development of the musculus tibialis posticus.

The influence of the squatting-habit is seen in some races in the formation of a facet upon the neck of the astragalus by the tibia. This is almost always absent in European races, although it has been found well developed in certain occupations, such as that of the tailor, etc.

Professor Dwight, of Harvard Medical College, believes that when a third trochanter of the femur is found the condition is one of true reversion and not an acquired variation, as it is found among the Sioux Indians in fifty per cent. and in the Laplanders to the extent of sixty-four per cent. Here we see the instance of an anomaly becoming the normal conditions in two nationalities. It is present in Swedes in thirty-seven per cent. of the cases, and like the condylar foramen is an ancient mammalian characteristic.

It might be said that the bones of the foot are developing on the inner and degenerating on the outer side, with slight loss of movement in the small toe. The anomalies in muscles, owing to various difficulties in tabulation and analysis, have never been adequately analyzed, but it may be stated generally that the number of muscles has been steadily increasing in the primates while the number of bones has been diminishing. In man the number of muscles has probably been increasing in the lower arm and diminishing in every other region; it is difficult to consider this, because some muscles revert to a former condition of greater specialization of movement. Under the usual physical conditions of life, degeneration is an extremely slow process, so much so that the change which is produced in the normal tissues can hardly be observed, but, given favorable conditions, degeneration can become very rapid; indeed some organs are so far on the down grade that they are supplied with nutrition for past services, performing none at present.

One symptom of decline is variability where the organ seems to show its own uselessness by being absent. Humphrey says: "The muscles which are most frequently absent by anomalies are in fact those which can disappear with least inconvenience, either because they can be replaced by others or they play an altogether secondary rôle in the organism."

The rudiment first becomes variable as an adult structure, then as a fœtal structure; then the absences slowly increase until they reappear as reversions; finally, they cease to revert and are lost. The varieties in the muscles of the thumb and carpus are very numerous, which would seem to indicate that those in this region are being gradually and progressively developed for specialized movements. Baker says: "On comparing the human hand with that of the anthropoids, it may be seen that efficiency is produced in two ways. First, increase in the mobility and variety of action of thumb and fingers. Second, reducing the muscles used mainly to assist prolonged grasp, they being no longer necessary to an organ for delicate work requiring constant readjustment.

The reduplication of the inferior tendon of the abductor pollicis (or extensor ossis metacarpi pollicis) (Wood), which is sometimes provided with a distinct muscle, points to the birth of a second abductor. Duval believes that the flexor longus pollicis in evolution between man and animals a little lower in organization reverts, as in the ape. Its place is supplied by a division of the flexor profundus, and the latter arrangement I have observed many times in the dissecting-room. Our grasping muscle, the palmaris longus, which varies greatly and like the plantaris of the leg has been replaced by other muscles, in negroes reverts to its former function by flexing the fingers, due to its insertion into the metacarpals; this variation may partially explain the grasping-power of infants, which is so great that the reflex contraction of the fingers will sustain their weight upon a slender crossbar.

The conclusions of Wood and Testut are that variability is independent of age or sex, of general muscularity, and of abnormal mental development. Wood found 981 anomalies in 102 subjects, and of these 623 were developed on both sides of the body, while 358 were unilateral. Statistics collected by Wood, between 1867–1868 in the dissecting-room of Kings College, London, upon 36 subjects (18 of each sex), show that there are more anomalies in the limbs than in the trunk, that anomalies are rare in the pelvis, that there were 292 anomalies in the arms to 119 in the legs, and that in both limbs the anomalies increase toward the distal segments, culminating in the muscles of the thumb, where they rise to ninety per cent.

The study of myology in the lower vertebrates shows that muscles arising from or inserted into bones in the vicinity of joints sometimes become metamorphosed into tendons near their attachments, and with this change there is tendency for alteration in the point of attachment. Thus a muscle originally inserted below a joint may eventually have its insertion above

the joint, and *vice versa;* this change is usually known as migration of muscles. The human ligaments have in most cases been evolved as the result of secondary changes in muscles adjacent to joints. Sometimes ligaments represent remnants of cartilaginous and even bony structures, the capsular ligament being usually derived from the periosteum.

In the knee-joint the adductor magnus, having shifted its insertion from the tibia to the femur, leaves part of its tendon as the internal lateral ligament; the external lateral ligament represents the tendon of the peroneus longus migrated from the femur to the head of the fibula. The ligamentum teres in the hip-joint was probably the tendon of the pectineus detached from the muscle during evolutionary changes. Again, the greater sacro-sciatic ligament was originally the tendon of origin of the biceps femoris. The lesser sacro-sciatic is derived from the fibrous regression of portions of the coccygeus. The sacro-sciatic ligaments represent the muscles which lift, depress, and wag the tail in those mammals furnished with such an appendage; and indeed these structures I have observed to be occasionally replaced by muscular tissue. The coraco-humeral ligament is derived from the original tendon of insertion of the pectoralis minor, and not infrequently the muscle is inserted into the lesser tuberosity of the humerus, the ligament being then replaced by the tendon of the muscle. The coraco-clavicular, the rhomboid, and gleno-humeral ligaments are probably derived from modifications of the subclavius muscle.

I append below a list of some anomalous muscles which have been observed once, twice, and even three times in cadavers during the last two years, and the presence of which, while unimportant in themselves, may act as a link in a chain of reasoning by investigators coming after, as they are not mentioned by most of the standard text-books on anatomy.

1. The abductor ossis metatarsi quinti arising from the outer tubercle of the calcaneum, inserted into the tuberosity at the base of the fifth metatarsal bone. According to Sutton this muscle is present in two out of every three subjects, and when not represented by muscular fibres its place is occupied by a band of fibrous tissue.

2. The extensor primi internodii hallucis longus, is usually an offset from the extensor proprius, but in one instance, arising separately from the fibula, it is inserted in the inner part of the base of the first phalanx of the great toe.

3. A fourth gluteal muscle, the gluteus quartus, which had its origin from the anterior part of the inferior gluteal ridge of the ilium and is inserted into the top of the great trochanter of the femur in front of the insertion of the gluteus minimus.

4. The peroneo-calcaneus internus arises from lower part of the posterior surface of the fibula and is inserted into the forepart of the inner surface of the calcaneum.

5. The rectus sternalis, arising from the sheath of the rectus abdominis, is inserted into the fascia covering the origin of the sterno-mastoid. According to Sutton this may be present on both sides.

It has been repeatedly denied that mutilations can have any influence in not only the production of anomalies, but also in that of congenital malformations, and in this connection I will quote the experimental evidence of the hereditary transmission of mutilations adduced by Dr. Charles E. Lockwood (and already quoted by Osborn). "Mice being used in this experiment, I selected a pair of white mice on account of their rapid breeding. I bred them in and in for ninety-six generations, as they breed every thirty days, and when they are thirty days old they are able to reproduce themselves. I destroyed all sickly and defective ones by breeding only the fittest. I bred all disease out of them, and had a pure-blooded animal, larger and finer every way than the original pair. In breeding their tails off, I selected a pair and put them in a cage by themselves, and when they had young I took the young and clipped their tails off. When old enough to breed I selected a pair from the young and bred them together, and when they had young I clipped their tails. I continued this breeding in and in, clipping each generation, and selecting a pair of the last young each time in seven generations. Some of the young came without tails, until I got a perfect breed of tailless mice. I then took one with a tail and one without a tail and bred them together, and by changing the sexes each time—a male without a tail, a female with a tail, and next a female without a tail and a male with a tail—I was finally rewarded with all-tail mice."

As the same laws (more or less modified) are supposed to govern the reproduction of the higher and the lower vertebrata, the significance of the above experiment will at least cause us to ponder upon analogical characters in the transmission of abnormalities, and in this connection comes the thought as to what are the relations existing between diseased structures and the suitable soil for the production or hereditary transmission of the same. It can hardly be contradicted that in certain diseases there is a reproduction of a suitable constitution in which by accident, direct infection, or otherwise the disease is reproduced in the offspring. The most common of these diseases is tuberculosis, and will not our knowledge of the processes involved in the production of this peculiar transmission of an anomalous type of health give us a more powerful weapon in fighting this disease than all the constituents of the various lists of advocates of serum therapy, etc.? As has been said by many observers, the best treatment of this, perhaps our most important disease, is that which begins at birth. In families in which tuberculosis is known to exist, we have almost invariably an anomalous conformation of the thorax, perhaps not as regards individual bones, but as a whole; and as has been previously stated this can be remedied, if treated at birth and afterward by massage, diet containing in addition to others proper bone constituents, proper hygienic surroundings, non-residence in crowded cities, etc., and as far as possible excluding family contagion by explaining to parents the contagious or infectious nature of this disease—in a word, all the prophylactic measures set down by other observers. In this connection may be noted Brown-Séquard's experiments on guinea-pigs, in which was shown not only the transmission of epilepsy but in certain individual cases a peculiarity or anomaly of constitution in which the disease, although not present at birth, could be produced by very slight causes. It would seem important to pay more attention to the anomalous physical conditions in which various micro-organisms produce ravishes of a diseased nature than to the life history of these microbes themselves, for it has been shown that without the proper soil these low forms cannot propagate or even exist. To the earnest observer the connection between mere physical conformation of not only the bony skeleton but of the muscular system, and the soil suitable for the production of various diseases, is seen to be much greater than would at first be supposed. The various abnormalities in heart structure would require much time to consider in full, but it will be remembered that in its development the organ passes through various stages, some similar to its normal development in inferior animals, so that malformations for the most part depend upon arrested development in some stage, and while most malformations are incompatible with prolongation of life, yet I believe that in some cases,

more numerous than commonly supposed, we see subjects who live normal if not prolonged periods. In going over a large number of cases there will be found individuals presenting well-developed murmurs, oftimes diagnosed as organic lesions, which would present at autopsy slight abnormalities rightly included under the heading of anomalies. Almost every clinical observer has, I think, seen some subjects well nourished and well developed physically presenting murmurs which are not anæmic, not due to habit such as tobacco, not affected by medication, yet persistent through life. Such a case suggests the possibility of a slight abnormality, either in the conformation of the heart as a whole or else insufficient valvular development. As our statistics are based generally upon so many hundred cases examined in this hospital, or so many thousand in that dissecting-room, we are apt to forget that by far the greatest number of persons dying from this or any other lesion are not examined at all.

The importance of anomalous structures to the operating surgeon is great in some regions. In the variety of enlargements of the thyroid gland in which we have an abnormal varicose condition, the varying bifurcations of the common carotid artery, the numerous variations in branches of the external carotid, to say nothing of enormously developed (as to size and number) trunks of the thyroid artery, have all to be considered in ligation of some or all of the latter. Dr. Mott mentions a case in which he operated and in which these latter branches were increased in number and as large as the end of the little finger. In hyperplastic and hypertrophic enlargements it would seem a wise procedure to curtail the amount of blood supplied to the organ. Thyroid enlargements occur very frequently in some of the lower animals and experimentation on the same is suggested.

128 West Fortieth Street.

THE ABSORPTION BY WATER OF FREE AND ALBUMINOID AMMONIA UNDER VARIOUS CONDITIONS

By N. KNIGHT, Ph.D.,

AND

W. M. BLANCHARD, A.M.,

Randolph-Macon College, Ashland, Va.

The water used in these investigations was obtained from a spring in the vicinity of Ashland, Va., known as "Rock Spring." Various analyses showed a constancy of the mineral constituents of the water. The small quantity of free and albuminoid ammonia it contains was determined from time to time and deducted from the amounts obtained in the following experiments. The ammonias were determined by a slight modification of the Wankyln-Nessler process. Two hundred cubic centimetres was usually distilled for a determination, and 50 c.c. nesslerized. This made it possible to repeat a test easily when it seemed desirable to do so. It should be understood that the ammonium nitrate and nitrite which are present in small quantities in the atmosphere are included in the albuminoid ammonia. The figures given express in every case the number of parts in a million.

Experimental Part.—Five hundred cubic centimetres of the water was placed in a porcelain evaporating-dish of two litres' capacity. The dish was thoroughly cleaned each time before using. The water was allowed to stand in a room occupied by two students as a study-room in the daytime and sleeping-room at night. The room was well ventilated by a wood fire and by open windows. After thirty-nine hours 500 c.c. more of the water was added to the dish to supply loss by evaporation. The whole was then allowed to stand twenty-one hours longer. Making the necessary corrections for the ammonia in the water, it contained: Free ammonia, 0.264; albuminoid ammonia, 0.400.

A litre of the water was placed in a room occupied by two students as a sleeping-apartment. The water remained six hours, from 11 P.M. to 5 A.M. The night was cool and the room was tightly closed. It contained: Free ammonia, 0.032; albuminoid ammonia, 0.048.

A litre of the water was placed in a fairly well-ventilated room, occupied by a student sick with the measles. After standing twenty hours the water contained: Free ammonia, 0.120; albuminoid ammonia, 0.048.

A litre of the water remained during the night in a ventilated sleeping-room of a private residence in the town. The room was occupied by two grown persons and a child. In the morning the water contained: Free ammonia, 0.120; albuminoid ammonia, 0.102.

Five hundred cubic centimetres of the water was kept for ten hours in an unventilated clothespress. It contained: Free ammonia, 0.447; albuminoid ammonia, 0.062.

Five hundred cubic centimetres of the water was placed in the chemical laboratory and allowed to remain three hours. No ammonia was used by the students during this time. It contained: Free ammonia, 0.624; albuminoid ammonia, 0.086.

Five hundred cubic centimetres of the water was left five and one-half hours in the chemical lecture-room. A class of forty occupied the room during one hour of the time. It contained: Free ammonia, 0.088; albuminoid ammonia, 0.038.

A litre of the water was allowed to remain seventeen hours in the biological laboratory of the college. It contained: Free ammonia, 0.200; albuminoid ammonia, 0.102.

Five hundred cubic centimetres of the water remained in the Latin lecture-room of the college six and one-half hours, during which there were recitations in progress about half the time. It contained: Free ammonia, 0.024; albuminoid ammonia, 0.030.

A litre of the water was placed early Sunday morning in the Ashland Methodist Church and left for twenty-four hours. Two services were held in the church, at each of which one hundred and twenty-five persons were present. The day was warm and the church was well ventilated by open windows. The water contained: Free ammonia, 0.148; albuminoid ammonia, 0.124.

On the following Sunday the foregoing experiment was repeated. The conditions were similar, except the day was cool and the windows were closed. The water contained: Free ammonia, 0.056; albuminoid ammonia, 0.142.

A litre of the water was allowed to remain twenty-four hours, beginning Sunday morning, in the Shiloh Baptist Church (colored) of Ashland. The building was poorly ventilated. Two services were held during the time, at each of which about fifty persons were present. The water contained: Free ammonia, 0.056; albuminoid ammonia, 0.166.

A litre of the water was placed in a urinal at 8:30 P.M. After nine hours it contained: Free ammonia, 0.744; albuminoid ammonia, 0.048.

Two litres of the water was placed in the large watercloset of the college at 10 A.M. After half an hour 500 c.c. was tested. It contained: Free ammonia, 0.056; albuminoid ammonia, 0.072.

After standing one hour another 500 c.c. of the water mentioned in the foregoing was withdrawn and tested. It contained: Free ammonia, 0.088; albuminoid ammonia, 0.032.

After two hours another 500 c.c. contained: Free ammonia, 0.264; albuminoid ammonia, 0.034.

After three hours another portion contained: Free ammonia, 0.356; albuminoid ammonia, 0.064.

On another occasion 500 c.c. was allowed to stand fifteen minutes in the same place. It contained: Free ammonia, 0.136; albuminoid ammonia, 0.048.

Five hundred cubic centimetres after five minutes contained: Free ammonia, 0.064; albuminoid ammonia, 0.062.

Five hundred cubic centimetres after one minute contained: Free ammonia, 0.048; albuminoid ammonia, 0.000.

To compare the amount absorbed by water standing in a shallow vessel, like an evaporating-dish, with the absorption in a narrow-necked chemical flask, the following experiments were made:

1. Five hundred cubic centimetres of the water was placed in a chemical flask, whose neck was one and one-half inches in diameter, and left for one hour in the watercloset of the college. It contained: Free ammonia, 0.064; albuminoid ammonia, 0.062.

2. After four hours under similar conditions it contained: Free ammonia, 0.080; albuminoid ammonia, 0.078.

3. Five hundred cubic centimetres of the water was placed in a well-ventilated sleeping-room, occupied by two students. After eight hours it contained: Free ammonia, 0.000; albuminoid ammonia, 0.006.

Five hundred cubic centimetres of the water in the evaporating-dish was allowed to remain ten hours in a cow stable. It contained: Free ammonia, 1.784; albuminoid ammonia, 0.235.

Five hundred cubic centimetres of the water remained six hours in a horseshed. It contained: Free ammonia, 0.593; albuminoid ammonia, 0.407.

The Absorption of Ammonia from the Air at Different Elevations.—A litre of water in the evaporating-dish was placed on the ground on the college campus. A similar portion was placed above this on a tower sixty feet high. Both remained ten hours. The former contained: Free ammonia, 0.080; albuminoid ammonia, 0.182. The latter contained: Free ammonia, 0.068; albuminoid ammonia, 0.102. This experiment was made on April 28th.

May 17th, placed 500 c.c. of the water on the college campus at 9 P.M., and the same quantity on the tower. After ten hours the former contained: Free ammonia, 0.312; albuminoid ammonia, 0.838. And the latter: Free ammonia, 0.040; albuminoid ammonia, 0.222.

The foregoing was repeated on May 18th, the temperature of the air having increased. The water on the ground contained: Free ammonia, 0.072; albuminoid ammonia, 0.142. The water on the tower contained: Free ammonia, 0.072; albuminoid ammonia, 0.086.

May 19th, the foregoing experiments were repeated. The water on the ground contained: Free ammonia, 0.176; albuminoid ammonia, 0.292. The water on the tower contained: Free ammonia, 0.048; albuminoid ammonia, 0.092.

May 20th, water placed as in the foregoing, on the ground, contained: Free ammonia, 0.064; albuminoid ammonia, 0.070. On a cloudy day 500 c.c. of the water remained five hours (from 12 M. to 5 P.M.) on the tower. It contained: Free ammonia, 0.160; albuminoid ammonia, 0.118.

May 27th, a sunny day, 500 c.c. of the water remained on the campus under the shade of the trees from 7 A.M. until 5 P.M. It contained: Free ammonia, 0.232; albuminoid ammonia, 0.686. The same quantity on the tower in the sunlight contained: Free ammonia, 0.008; albuminoid ammonia, 0.038.

Ammonia in Rain Water.—Previously to May 12th there had been almost no rainfall for several weeks. On the night of the 12th there were frequent showers. At five o'clock, on the morning of the 13th, the evaporating-dishes were placed in the open air. There was a gentle rainfall during the day. Five hundred cubic centimetres of water had collected at 1 P.M. It contained: Free ammonia, 0.128; albuminoid ammonia, 0.230.

At 3:15 P.M. another 500 c.c. had collected. It contained: Free ammonia, 0.088; albuminoid ammonia, 0.252.

Later, after clear weather for several days, there were heavy rains. Five hundred cubic centimetres of the water caught at the beginning of the shower contained: Free ammonia, 0.160; albuminoid ammonia, 0.168.

After it had rained for some time, 500 c.c. showed: Free ammonia, 0.144; albuminoid ammonia, 0.078.

Conclusions.—These conclusions, arrived at also by other experimenters, seem justified from the foregoing work. The ammonias may be regarded as a type of the impurities in the air.

1. The purity of the air increases with the elevation.

2. The sunlight is a purifier of the air.

3. The amount of absorption depends upon the surface exposed.

4. The great absorbing-power of water and its purifying effect upon the air of a room.

5. The beneficial effects of lakes, rivers, and other large bodies of water in purifying the air of the surrounding country.

It is purposed to investigate the absorbing-power of milk and other liquids, for comparison with water.

Progress of Medical Science.

Malarial Disease Prevented by Small Doses of Quinine.—Laveran reviews the reports of many medical officers in charge of the health of bodies of European and American men exposed to severe malarial influences (*The New York Medical Journal*). His conclusion is that quinine usually proves very potent in preventing or at least mitigating malarial disease, even in very unhealthful localities. Against its use the objection has been made that daily administration of this drug induces attacks of indigestion, and that quinine becomes less potent in a given case if administered constantly, the system becoming habituated to it. Yet these objections are not sound. A dose of from one-fifth to three-tenths of a gram a day can be employed for months with impunity. Quinine destroys the causative microbes by its power as a parasiticide. The microbes of paludism that chance to get into the blood of a person who has been treated preliminarily by the small preventive doses find it a medium wholly or quite unfavorable to their development. At the most, they develop only with difficulty. The daily dose should not exceed three-fifths of a gram nor be less than a seventh of a gram. Some prefer a dose of one gram thrice weekly. To procure a rapid absorption, the hydrochloride is preferable to the sulphate, and is better supported. The best time to take quinine is at mealtimes. The best way is to dissolve it in wine, although cachets or pills suffice. If added to coffee, that precipitates a portion of the quinine.

Cancer.—If we suspect cancer in a woman I fear we often go too far in concealment of the danger from the patient.—WALKER.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 43, 45, & 47 East Tenth Street.

New York, October 2, 1897.

OVERCROWDING OF THE MEDICAL PROFESSION.

SOME few months ago the *Daily Telegraph* in London took up the matter of dispensary abuse, and the subject was thoroughly ventilated in the pages of that journal. Now the *Standard* is following in the footsteps of its rival, and has opened its columns to a discussion on the overcrowding of the medical profession. Many harrowing tales are being told of the straits to which struggling practitioners are reduced in their efforts to gain a living. One medical man writes to say that the average income of a doctor in Great Britain at the present day does not reach the sum of $1,200 yearly; another one dwells upon the much-vexed point of the way in which hospitals are made use of by persons for whom they were never meant, and many instances are quoted to bear out this contention. This correspondence comes, as was doubtless intended it should, at a most appropriate season. The medical schools are on the point of reopening. It is certainly for the ultimate benefit of those about to enter the profession of medicine that they should be made to understand the difficulties that they will have to encounter and the hard road they must expect to travel, before any sort of a goal is reached. It would appear, too, that the position of the medical man here is more or less identical with that of his English brother, for while in America the fees are higher, on the other hand the profession is perhaps even more crowded here than in England. *The Lancet*, referring to the outlook so far as medical students are concerned, says that the facts of the case should be present in the mind of every young man who contemplates entering the medical profession. To men who realize the dignity of medical service and of the medical calling, our contemporary says, there is still room in our profession; but those who look for their reward in large incomes will do well to pause. That the present unsatisfactory position of the medical profession, both as regards the overcrowding and the abuses in connection with it, should be openly discussed and kept before the public in every possible way, is to the best interests of its members. The more fully a grievance is aired, the more quickly is it likely to be remedied.

ASEPTIC BARBERING.

THE sanitary authorities of Paris have instituted a very important regulation respecting aseptic barbering, which deserves to be imitated in every town and city in which the knights of the scissors and the wielders of the razor are to be found. The only strange thing is that the regulations regarding cleanliness in hands and instruments have not been enforced long ago. There is hardly a person who has not been reminded of the necessity of the measure. Even the ordinary patron appreciates the glaring fact that at every *séance* he is liable to some form of skin disease of the scalp or face, communicated more or less directly by a previous customer through the proverbial carelessness of the fussy and oftentimes positively dirty manipulator. In Paris barbers are now required to use aseptic tools, sterilized towels, metallic combs, and, above all, their hands are to be kept scrupulously clean by being washed for every sitter. Nothing could be simpler, nothing more popular, and certainly nothing safer. Why could not our own health board, always so alert in serving the community, demonstrate its usefulness in this direction? It would be certain to have the entire public, excepting possibly that part composed of dirty and lazy barbers, on the side of such a very necessary reform.

THE PUNISHMENT OF UNLICENSED PRACTITIONERS.

THERE seems to be some doubt in the minds of certain members of the Medical Society of the County of New York regarding the rights of a so-called bone-setter to practise his alleged profession in New York. This delectable individual, who modestly confesses the possession of a peculiar sensitiveness of touch and a remarkable manipulative power, has been giving such public exhibitions in smoothing bones in place and in working out the stiffness of creaky joints that he has now a flourishing clinic of his own and may seriously affect the business of many of the free dispensaries. Although at best his method of work is a rude and unscientific form of massage, his claim for reducing dislocations thereby would, it seems to us, clearly place him within the present law against practising without a license. Reducing dislocations is certainly a recognized surgical procedure, and even an attempt in that direction would make the pretender clearly indictable. Comparatively speaking, however, it would appear to be hardly to the purpose to make a martyr of this blatant quack, so long as the society in question quietly winks at the many abortionists and others of that ilk who openly bid for business in all the daily papers. At least it does not seem to have the power to touch the worst of all quacks.

The Contagious Period of Whooping-Cough.—According to the *British Medical Journal*, Dr. Weill, a French physician, has made a series of experiments which indicate that whooping-cough is contagious only before the patient begins to whoop.

THE CONTAGIOUS-DISEASES ACT IN INDIA.

It has been decided to bring again into force in India the "contagious-diseases act for women." This decision has been arrived at in consequence of the frightful increase of venereal diseases among the English army in that country. That the situation is one of extreme gravity statistics easily prove. In 1895 the admissions into hospitals for venereal diseases were 36,681, and of these, 22,702 were cases of syphilis. The ratio for primary syphilis had increased one hundred and thirty-seven per cent. since 1887, and secondary syphilis was in 1895 four times more prevalent than in 1873. The government does not propose compulsory examination, but it feels that some decided steps must be taken to prevent the army from being decimated by syphilis, and also that innocent women and children must be protected against the risk of infection by this disease. This resolution on the part of the authorities has raised a storm of indignation and protest among a small but noisy section of the British public. Nevertheless, in the ranks of those averse to the measure occur some notable names, and women especially are up in arms against it. The medical men of Great Britain as a body concur in the advisability of prompt and effective action being taken to endeavor to check the ravages of this insidious affection, though even with them there are exceptions.

Dr. Charles Taylor, in an address on the subject, published in the *Medical Times and Hospital Gazette*, tries his hardest to prove that alteration in the present law is quite unnecessary, and he goes to absurd lengths in his attempts to show that all venereal diseases are comparatively innocuous. After dismissing gonorrhœa as a complaint so trifling as not to be worthy of discussion, he proceeds to whitewash syphilis. The great majority of patients who contract true or constitutional syphilis, he says, are readily and permanently cured, and then do not transmit disease to their offspring. He then goes on to say: "Let me lay a little evidence before you in proof of this last assertion, *i.e.*, that true syphilis is not such a formidable disease as we have been led to suppose, and that in the great majority of cases it is so easily controlled that we need not fear any of its manifestations. Of course, we all know that syphilis has been on the wane all over the world for centuries; that it has declined both in strength and virulence in every country under the sun; that the sibbens of Scotland, the radesyge of Norway, and the yaws of Africa are, practically speaking, things of the past; that the diseased bones, the sloughing phagedena, and serpiginous ulceration are no more to be seen; and that a man may practise —in ordinary general practice—for a lifetime without meeting with a single case of malignant or tertiary syphilis." Dr. Taylor then quotes several authorities in support of these contentions, among them Jonathan Hutchinson.

Notwithstanding this eloquent defence of syphilis, it will be difficult to convince a very large number of those qualified to pass an opinion that it is so harmless a disease as Dr. Taylor tries to demonstrate it to be. It is probably true that at one time the gravity of syphilis was exaggerated, and no doubt with modern rational treatment it is not the dread scourge it was in bygone days; but the contention that it is a more or less harmless complaint, if advanced by any man of ability or authority, would be pernicious in its consequences. The line of opposition that Dr. Taylor takes against the bill is not only that it is unnecessary, but that it tends to curtail the liberty of the subject, as well as to the creation of what he terms a far worse and more fatal disease, "syphiliphobia." Doubtless many objections can be urged against this "contagious act," but a very strong point in its favor is that it was effective when in force formerly, and until better methods have been devised the government of India will be found to have taken the wisest course in again adopting the system that worked well in the past. Of course, this is a very different thing from the licensing and compulsory examination of prostitutes in cities, which many sociologists and physicians regard as useless.

News of the Week.

The Alvarenga Prize of the College of Physicians of Philadelphia for 1897 has been awarded to Dr. Joseph Collins, of this city, for an essay entitled "Aphasia: A Contribution and Critical Study."

American Electro-Therapeutic Association.—The seventh annual meeting of the American Electro-therapeutic Association was held at Harrisburg, Pa., on September 21st, 22d, and 23d. Dr. William T. Bishop, of that city, presided. An address of welcome was delivered by Mayor Patterson, to which reply was made by Dr. Robert Newman, of New York City. Among the papers read on the first day were the following: "Sources of Atmospheric Electricity," Dr. R. J. Nunn, of Savannah, Ga.; "Some Thoughts and Suggestions on *x*-Ray Work," Dr. Eugene R. Corson, of Savannah, Ga.; "A New Electrode for Use with the Static Machine," Dr. Lucy Hall-Brown, of Brooklyn, N. Y.; "Some Considerations Relative to the Therapeutic Application of the Current," by invitation, Dr. George E. Bill, of Harrisburg. On the second day Dr. Eli H. Coover, of Harrisburg, read a paper on heart failure in cardiac diseases due to defective circulation; and Dr. Margaret A. Cleaves, of New York City, one on expenditures of electrical energy. On the third day the following papers were read: "What Has Electricity Accomplished in the Treatment of Mental Diseases?" Dr. Robert S. Newton, of New York City; "Mental Electricity," Dr. W. S. Watson, of Fishkill-on-Hudson, N. Y.; "Electricity in Orthopædic Practice," Dr. L. A. Weigel, of Rochester, N. Y.; "A New Electrode, Preventing the Diffusion of the Current;" "Palliative Electric Treatment of the Tic Douloureux of the Face;" "The Action of the Roentgen Rays on the Vitality and Virulence of Koch's Bacilli in Cultures," Dr. J. Bergonie, of Bordeaux, France. The following officers were elected for the ensuing year: *President*, Dr. Charles

R. Dickson, of Toronto, Ont.; *Vice-Presidents*, Dr. F. S. Shavoir, of Stamford, Conn.; Dr. Caleb Brown, of Sac City, Iowa; *Secretary*, Dr. Henry Gerin, of Auburn, N. Y.; *Treasurer*, Dr. Robert J. Nunn, of Savannah Ga.; *Executive Council*, Dr. Robert Newman, of New York; Dr. G. Betton Massey, of Philadelphia; Dr. W. T. Bishop, of Harrisburg; Dr. W. J. Morton, of New York City; Dr. W. J. Herdman, of Ann Arbor, Mich. The next meeting is to be held at Buffalo, N. Y.

Hog Cholera in Delaware.—Hog cholera is epidemic in the northern part of Kent County, Del., scarcely a single animal escaping infection.

Generous Bequests.—By the will of the late Mrs. Eliza W. S. P. Field, who died recently in England, $10,000 is bequeathed to the Philadelphia Home for Incurables, for the endowment of two free beds; $500 to the Germantown Hospital and Dispensary; $1,000 to the Children's Hospital of Philadelphia; and to the University of Pennsylvania $10,000 in trust for the establishment of two scholarships, the income to be used to defray the expenses of such ambitious and diligent students from the Central High School as the trustees of the university may deem worthy; $5,000 for the endowment of a free bed in its hospital; $5,000 for the endowment of a free bed in its Maternity Hospital; $20,000 in trust for the general uses and purposes of its hospital; $20,000 in trust, the income to be devoted to the Maternity Hospital, and the further sum of $20,000 for the general uses of the university. The testatrix bequeathed her residuary estate also to the university.

Proper Dispensary Fees.—At last New York has had filled a "long felt need," as the nostrum advertisement usually puts it. We have contended that the dispensary should provide every attraction for the patient and make an effort to draw in clients from every walk in life. During the past week notices have been sent out of a new dispensary which should prove an attraction to a large class of dispensary goers. The fee for treatment is placed at $25. This will naturally keep away undesirable individuals and secure to patrons a certain exclusiveness, often too much neglected in the institutions already established. Since there must always be a "very best" for the ultra-exclusive set, we may look for some rival institution in which the entrance fee has been advanced to $50. The one which has taken the initiative in establishing a proper fee is for the exclusive treatment of inebriates.

An Unfavorable View of the Montreal Meeting.—The sixty-fourth convocation of this, the greatest of all Anglo-Saxon medical gatherings, has passed into history. The city of Montreal as a corporation, and the medical profession of the city, "did themselves proud" in matters of hospitality. The attendance was large, over eight hundred registering; and a large number of medical men gathered besides, ostensibly to attend the meeting but never registered, their aims being of a social rather than a scientific character. The greatest drawback was the lack of proper hotel accommodations; indeed, for a city of the pretensions of Montreal such were woefully deficient. The general addresses, that of the president excepted, were decidedly mediocre, being "chestnutty" in flavor, and in one instance so self-laudatory and egoistic as to provoke most unenviable comment. The papers presented to the sections, with few exceptions, were of like character; remarkably, not a single new idea was evolved or even suggested. Their tone was such they might pass for papers read at any of half a dozen meetings of like character, convened during the past five years. Even the discussions were flat, stale, and unprofitable, hence the attendance daily became more meagre—so meagre in fact that it was a common cause of comment. Nevertheless the British Medical Association was a success—a great success—as a social body. Scientifically it was mediocre, repetitious, heavy, and wearisome; dull as ditch water, relieved only by the manifest attempts of the little chaps to be thought big and the larger ones to grow greater in the estimation of their fellow-men.—*The Medical Age.*

A Physician Crazed by Sympathy.—Dr. T. M. Angstadt, a graduate of Jefferson Medical College practising in Nova Scotia, found himself baffled by a perplexing case for which he was able to do nothing. The patient suffered greatly, and no medicines or even surgical treatment availed anything. The thought of the patient's sufferings and of his own powerlessness so weighed upon the physician's mind, that he killed himself, after making a will in which he devised all his property, amounting to about $2,000, to the patient.

An Old People's Convention.—The old folks of Manchester, Vt., hold occasional meetings for the purpose of comparing notes and exchanging reminiscences. The latest was held there on September 24th. Of one hundred and fifty invitations extended to persons over seventy years of age, over one hundred responded, half of them being between seventy and eighty. Two were over ninety, the oldest person present being ninety-three years old, and the second oldest ninety-one years of age. Of the one hundred and ten persons who attended the first reunion in 1890, more than half are dead. At the reunion two years ago more than one hundred registered, twenty-two of whom are dead. The next reunion will be held in two years.

Dr. Eugenio Sanchez Agramonte, a surgeon in the army of the Cuban republic, is at present in New York, and was recently entertained at dinner by the Oscar Primelles Club, a society established to aid the sick and wounded in the patriot army.

A Typhoid Epidemic at Maidstone.—It is reported that an alarming outbreak of typhoid fever has occurred at Maidstone, in England, over six hundred people being ill with the disease at the present time. The epidemic is attributed to pollution of the water supply by drainage from an encampment of hop pickers, among whom several had been sick with typhoid.

The Plague is steadily increasing again in the Bombay presidency, the strange neglect of the sani-

tary authorities having permitted the disease to creep unobserved from hamlet to hamlet until a wide area has become affected. The newspapers assert that the withdrawal of the medical officers for service with the troops on the frontier will entail consequences in the way of a recrudescence of the plague infinitely more disastrous than anything happening on the frontier.

A Charge of Inhumanity against New York Hospitals.—In the management of ambulance cases the ambulance first arriving at the spot where an individual requires immediate medical or surgical aid is supposed to take the patient to the nearest hospital; but a recent case, in which a man had his skull fractured in the vicinity of Roosevelt Hospital and was taken by an ambulance of that hospital a long distance to Bellevue, where he died in a few hours, has called renewed attention to the practice of the large private hospitals maintaining an ambulance service, all of which receive more or less assistance from the public funds, of sending dying patients, sometimes taken directly from their own wards, to the public hospitals. Naturally, such transfers are not, as a rule, beneficial to the patient; but it is highly desirable that the death rate in such hospitals, which depend to a greater or less extent on private contributions for their support, should be kept as low as possible, in order that in their annual reports a favorable showing may be made to their patrons.—*Boston Medical and Surgical Journal.*

Dr. Charles E. Nammack has been appointed visiting physician to the non-collegiate division of Bellevue Hospital.

Salt in the British Navy.—The British naval authorities have just added salt to the rations of the sailors, that necessary condiment having hitherto been denied them except as they paid for it themselves.

American Academy of Railway Surgeons.—The fourth annual meeting of this society will be held in Chicago, October 6, 7, and 8, 1897. The president of the academy is Dr. L. E. Lemen, of Denver; the secretary, Dr. D. C. Bryant, of Omaha.

The Turkish Troops in Thessaly are suffering greatly from sickness. Ten thousand soldiers have been sent home or are awaiting the means of transport to Constantinople on account of invalidism. Typhoid fever is the disease causing the greatest morbidity and mortality.

The Fourth French Congress of Internal Medicine will be held at Montpellier on April 12, 1898, and following days. The questions proposed for discussion are: (1) "Clinical Forms of Pulmonary Tuberculosis," to be discussed by MM. Bard, of Lyons, Vergely, of Bordeaux, and Revilliod, of Geneva; (2) "Microbic Association and Mixed Infections," to be discussed by MM. Spillmann, of Nancy, Widal, of Paris, and Malvoy of Liége; (3) "The Therapeutic Utilization of Organs with an Internal Secretion," to be discussed by MM. Lemoine, of Lille, Mosse, of Toulouse, and Cerenville, of Lausanne.

Bellevue Hospital Medical College.—The Bellevue Hospital Medical College was thrown open, September 28th, for the first time since the fire which almost destroyed it. The building has been almost entirely reconstructed, being provided with a new dissecting-room, an almost new lecture-room, a museum, and a new office for the clerk. The most important changes in the faculty are: Dr. Edward G. Janeway succeeding the late Professor Lusk as president, Dr. Henry C. Coe succeeding Professor Lusk as clinical professor of gynæcology, Dr. Henry H. Rusby succeeding Prof. Herman M. Biggs as professor of materia medica and pharmacology, and Prof. John A. Mandel succeeding Prof. Ogden B. Doremus as professor of chemistry.

Death of Dr. W. H. Booth.—Dr. W. H. Booth, a prominent physician of Utica, N. Y., died at the Murray Hill Hotel, September 25th, after a brief illness. Dr. Booth had been a sufferer from a chronic disease for years. He was on a pleasure trip with Mrs. Booth when fatally stricken. He was forty-five years old.

Tri-State Medical Society.—The ninth annual meeting of the Tri-State Medical Society of Alabama, Georgia, and Tennessee will be held in Nashville, Tenn., Tuesday, Wednesday, and Thursday, October 12, 13, and 14, 1897.

Mississippi Valley Medical Association.—The twenty-third annual meeting of the Mississippi Valley Medical Association will be held in Louisville, Ky., October 5, 6, 7, and 8, 1897.

The Miami Valley Medical Society (Ohio) will hold its fortieth semi-annual meeting in Loveland, Ohio, Tuesday, October 12, 1897.

Navy Department, Bureau of Medicine and Surgery, Washington, D. C.—Changes in the medical corps of the United States navy for the week ending September 25, 1897. September 18th.—Assistant Surgeon C. E. Riggs detached from the New York navy yard October 4th, and ordered to the *Newport* October 4th. Passed Assistant Surgeon J. F. Leys detached from the *Helena* September 20th, and ordered to the *Vesuvius*. Surgeon N. H. Drake, ordered to the *Minneapolis*, *Columbia*, and other vessels in reserve at League Island, Pa. Passed Assistant Surgeon M. F. Gates detached from the *Minneapolis*, on relief, and ordered to the Boston Hospital. Surgeon G. P. Lumsden detached from Port Royal, on relief, and ordered to special duty attending officers at Norfolk, Va. Passed Assistant Surgeon G. A. Lung detached from the Boston Hospital, on relief, and ordered to naval station, Port Royal, S. C. Passed Assistant Surgeon M. S. Guest detached from the *Vesuvius*, and ordered to the *Helena* September 20th. September 23d.—Surgeon F. Rodgers, when detached from Boston navy yard, ordered home and to be ready for sea. Surgeon H. E. Ames, ordered to the navy yard, Norfolk, Va., October 2d. September 24th.—Assistant Surgeon M. S. Elliott detached from the *Indiana* and ordered to the *Porter*.

Reviews and Notices.

BRAITHWAITE'S RETROSPECT OF MEDICINE. Vol. CXV. January to June, 1897. London: Simpkin, Marshall, Hamilton, Kent & Co.

THIS publication keeps up its usual high standard, and as a handy reference book cannot be too highly recommended.

TRANSACTIONS OF THE MEDICAL SOCIETY OF THE STATE OF NEW YORK. For the year 1897.

THE ninety-first annual meeting of this society was held at Albany in January last, under the presidency of Dr. James D. Spencer, of Watertown, and is reported in the volume under notice. A feature of this volume is the report of discussions in which different speakers handle special subjects.

PROBLEMS OF NATURE. Researches and Discoveries of GUSTAV JAEGER, M.D., Selected from his Published Writings. New York: Brentano. 1897.

DR. JAEGER has made for himself a world-wide reputation as the introducer of a special form of underclothing, but as a man of science he is little known—at any rate to English-speaking people. It appears, however, that he is an investigator in the field of organic science as well as a deep student of philology. His work is well worth a perusal.

TRANSACTIONS OF THE ASSOCIATION OF AMERICAN PHYSICIANS. Twelfth Session, held at Washington, D. C. Vol. XII. 1897.

THIS the twelfth volume of these transactions is fully as interesting as the preceding volumes. The account of a case of acromegaly with numerous excellent illustrations is especially worthy of note.

LIPPINCOTT'S MEDICAL DICTIONARY. A Complete Vocabulary of the Terms Used in Medicine and the Allied Sciences, with their Pronunciation, Etymology, and Signification, including much Collateral Information of a Descriptive and Encyclopædic Character. Prepared on the Basis of Thomas' Complete Medical Dictionary. By RYLAND W. GREENE, B.A., with the Editorial Collaboration of JOHN ASHHURST, JR., M.D., Barton Professor of Surgery and Professor of Clinical Surgery in the University of Pennsylvania; GEORGE A. PIERSOL, M.D., Professor of Anatomy in the University of Pennsylvania; JOSEPH P. REMINGTON, Ph.M., F.C.S., Professor of Theory and Practice of Pharmacy in the Philadelphia College of Pharmacy. Complete in one imperial octavo volume of about 1,100 pages. Philadelphia: J. B. Lippincott Company. 1897.

THIS dictionary, although stated by the editor to be based on Thomas' dictionary, is practically a new work, as a brief comparison of the two shows. A careful comparison of the book with several of the most popular medical dictionaries and also a practical test of it in daily use during a period of several weeks, have convinced us of its completeness, the discriminating nicety of its definitions, and its general excellence as an authoritative guide. The system of diacritical marks for indicating pronunciation is altogether too complicated for a work of this kind, and would be very apt to puzzle or even mislead one whose previous education has been such as to make him dependent upon a dictionary for his pronunciation. This is, however, a matter of minor importance, and detracts in no way from the value of the work as an authority for the definition of medical terms.

TWENTIETH CENTURY PRACTICE. An International Encyclopedia of Modern Medical Science by Leading Authorities of Europe and America. Edited by THOMAS L. STEDMAN, M.D., New York City. In Twenty Volumes. Vol. IX., Diseases of the Digestive Organs. New York: William Wood and Company. 1897.

THE list of contributors gives a fair idea of the worth of this volume. It includes the names of Ewald, Franks, Gibney, Gioffredi, Kümmel, Mikulicz, Murphy, Semmola, Stengel, and Walker.

The list of subjects embraces "Local Diseases of the Mouth," "Diseases of the Intestines," "Hernia," "Diseases of the Spleen," "Diseases of the Liver," "Diseases of the Gall Bladder," and "Movable Kidney."

Mikulicz and Kümmel are already known as authorities upon mouth diseases, and they have conjointly produced a very readable monograph whose interest is increased by the illustrations. Carl Ewald's chapter on intestinal diseases does not include those associated with the various infectious processes, nor those due to parasites, these as well as hernia having received consideration in another portion of the work. Ewald's words carry weight in this special branch, and the chapter is written in the author's characteristically impressive style.

Mariano Semmola and Carlo Gioffredi have combined their efforts in the production of the chapter on diseases of the liver, which covers three hundred and thirty pages, and includes all the biliary and hepatic affections not elsewhere discussed. Dr. John B. Murphy, of Chicago, follows with an excellent chapter on the gall bladder, which is in a manner supplementary.

Echinococcus of the liver was included, if we mistake not, in a chapter on hydatid disease in a preceding volume, but as the present one is short no great harm will be done, we being able to compare the views of two different authors whose observations have been made in different geographical quarters. The concluding chapter of this very interesting volume is on "Movable Kidney," by the pen of Kendal Franks, of Johannesburg, S. A. Republic, formerly of Dublin, and well known for his excellent work in this obscure subject. The manner in which the author has condensed the present stock of available information concerning movable kidney amply justifies his selection by the editor.

SWEDISH MOVEMENTS OR MEDICAL GYMNASTICS. Translated from the text of T. J. HARTELIN, by A. B. OLSEN, M.D.

This is simply a monotonous enumeration of the several movements to be performed to obtain certain beneficial results. The book will be a great aid to the professional masseur or the mechano-therapeutist, but the general practitioner will find little in it to engage his attention. It is an almost literal translation, in consequence of which the translator's English suffers severely. Part second, on "Diseases and their Treatment by Medical Gymnastics," contains much that is good, inasmuch as it demonstrates that a great number of affections will be more benefited by judiciously applied exercise than by the administration of drugs.

TWENTIETH CENTURY PRACTICE. An International Encyclopedia of Modern Medical Science by Leading Authorities of Europe and America. Edited by THOMAS L. STEDMAN, M.D., New York City. In Twenty Volumes. Vol. XI., Diseases of the Nervous System. New York: William Wood and Company. 1897.

IN putting out vol. xi., the editor of this century-anticipating work must have much the feeling of the mountain climber when he has passed the half-way house. Not so with the writers, for the names are new to the work and to judge by their productions they have entered with fresh vigor upon the task.

Bruns, of Hanover, and Windscheid, of Leipsic, have given an extensive and satisfactory account of diseases of the spinal cord. Möbius, of Leipsic, treats of tabes dorsalis in about eighty well-written pages. Strümpell, of Erlangen, has a chapter entitled "The Combined System Diseases of the Spinal Cord." By "system diseases" the author means affections in which only nerve cells and nerve fibres, that is, neurons which have a definite physiological function, are attacked. This chapter is very short but includes "Friedreich's Disease" and "Hereditary Spastic Spinal Paralysis."

"Pain" is elucidated by Dr. Witmer, of Philadelphia, and Dr. Lloyd, of the same city, has accomplished the difficult task of describing in an acceptable manner the diseases of the cerebro-spinal and sympathetic nerves. This chapter takes up about one-half of the volume's space. Two hundred and forty bibliographical references are given.

Trophoneuroses, excluding scleroderma, acromegaly, and adiposis dolorosa, are described by Dr. Mills, of Philadelphia, while Dr. Dercum, of the same city, takes up these latter subjects.

This is the second volume upon the nerves, but being freely illustrated is rather more attractive on this account

than the first. It may be safely predicted that if the succeeding volumes of the second half of this series come up to the standard set by Vol. XI. the work as a whole will prove a successful undertaking to the publisher, and will surely be a credit to the editor.

TRANSACTIONS OF THE SOUTHERN SURGICAL AND GYNECOLOGICAL ASSOCIATION. Vol. IX. Published by the Association.

THIS is the report of the ninth session of the association, held at Nashville, Tenn., November 10, 11, and 12, 1896, under the presidency of Dr. George Ben Johnston. This is one of the most interesting volumes published by this association, containing over four hundred and seventy pages, well printed and well edited.

TRANSACTIONS OF THE AMERICAN PEDIATRIC SOCIETY. Vol. VIII. Reprinted from the *Archives of Pediatrics*. 1896.

THIS is a report of the eighth session of the association, held in Montreal, Canada, May 25, 26, and 27, 1896, under the presidency of Dr. Samuel S. Adams. This volume contains thirty-five papers on subjects that are of interest to the general practitioner.

SIXTEENTH REPORT OF THE STATE BOARD OF HEALTH OF WISCONSIN. 1895–96. Madison Democrat Printing Company, State Printer. 1897.

THIS little volume is made up largely of extracts from health officers' correspondence.

A COURSE OF PRACTICAL HISTOLOGY. By EDWARD ALBERT SCHÄFER, LL.D., F.R.S., Jodrell Professor of Physiology in University College, London. Philadelphia: Lea Bros. & Co. 1897.

IN the preface Dr. Schäfer explains the plan of this work. He says that "it is designed to afford those engaged in practical histology plain and intelligible directions for the suitable preparation of the animal tissues, so that they may be able to carry on their histological studies without the constant presence of a teacher." This design is carried out in the most satisfactory manner; the descriptions throughout the book are plain, clear, and concise, and a student by reading and digesting the contents should gain a good insight of practical histology.

URINALYSIS: A GUIDE FOR THE BUSY PRACTITIONER. By HEINRICH STEIN, Ph.D., M.D. New York: E. R. Pelton. 1897.

THIS little book, as its full title denotes, is intended for the use of the general practitioner, and, judging from a perusal of its pages, should excellently fulfil the object for which it is intended. The reading-matter is thoroughly to the point, and equal to the requirements of an ordinary practice. Each printed page of this book alternates with a blank one, very useful for notes, a device that in the case of text-books might be more generally adopted.

A PRACTICAL MANUAL OF DISEASES OF WOMEN AND UTERINE THERAPEUTICS FOR STUDENTS AND PRACTITIONERS. By H. MACNAUGHTON JONES, M.D., M.Ch., M.A. (Hon. Caus.), F.R.C.S. Ireland and Edinburgh. 7th Edition. New York: William Wood and Company. 1897.

THAT this work has since 1884 gone through several editions is a sufficient guarantee of its worth and popularity. There is probably at the present time no subject on which it is more difficult to write a really up-to-date text-book than that of diseases of women. Opinions of gynæcological authorities differ so widely and every year sees so great advances in abdominal surgery, that views which might be taken as almost conclusive but a short time ago are to-day regarded as obsolete. Dr. Jones has surmounted in the most able manner all the difficulties with which he has had to grapple, and in the present edition of his work produced a book which is a complete survey of the position of gynæcology of the day, including in its pages all the recent progress made in this branch of medicine and surgery. Possibly the most interesting reading is that on the pathology of the cysts of the ovary. In connection with this subject the author quotes Mr. Bland Sutton, to whom he acknowledges his indebtedness. One feature which deserves mention is the number of really excellent illustrations and plates; in fact, the book is in every respect a credit to the publishers.

Society Reports.

TWELFTH INTERNATIONAL MEDICAL CONGRESS.

Held in Moscow, August 19, 20, 21, 22, 23, 24, 25 and 26, 1897.

[illegible]

SECTION IN MEDICINE.

[illegible]

Fourth Day—Tuesday, August 24th.

The Causes of Essential Chlorosis. — DR. GILBERT, of Paris, read the paper. Seven years ago, the speaker said, he proposed the theory of arterial hypoplasia; to-day he returned to its defence. The genital theory was proposed by Hippocrates, who attributed the disease to the retention of blood in the uterus. The idea that chlorosis may be an expression of an intoxication caused by suppression of the menstruation has also been formulated. Montard-Martin has adopted this theory; more recently it was defended by Charrin, and still later by Spillmann and Etienne. These last observers do not attribute chlorosis solely to amenorrhœa, but say the cause is a pathological condition of the ovaries which prevents ovulation and prevents too the secretion of the glands; in this latter we see an analogy to the important rôle of the testicle in general nutrition. But this does not explain the cases of chlorosis in boys nor the absence of chlorosis in women who have undergone castration. Sydenham and Morton were the first promulgators of the nervous theory, but Trousseau was its chief defender. The latter contended that the nervous impression produced was never lost even though the blood condition entirely disappeared, in fact even when later there was plethora.

The defenders of the digestive theory differ greatly among themselves. Stockman says the condition is due to the lack of iron in the food, Luton ascribes it to ulcer of the stomach, Meinert to gastroptosis caused most frequently by the corset, Forchheimer to changes in the small intestine causing a reduction in the formation of hæmoglobin, Duclos and Andrew Clark to constipation causing an autotoxæmia, Bean and Mongour to dyspepsia in its general sense. The liver has been accused by Fox, who attributes chlorosis to atrophy of this organ; while Clement says it is hypertrophy of the spleen.

Vascular Theory.—The author divides the cases of chlorosis into three classes: (1) Chlorosis with vascular hypoplasia without change in the sexual apparatus; (2) Chlorosis with vascular hypoplasia and excessive development of the genital apparatus; (3) Chlorosis with vascular hypoplasia and defective development in the genital apparatus. Even though later researches may show that the vascular hypoplasia is not constant, the lesions of the vessels and the heart will occupy nevertheless a prominent place in the pathological anatomy of chlorosis. The whole arterial system is affected, but this pathological condition is particularly appreciable in the aorta which is modified in its calibre, its structure, and in the manner of emergence of its collaterals (aorta chlorotica). The artery is narrow, infantile; its lumen scarcely admits the little finger and the abdominal portion has only the dimensions of a normal crural artery. Its walls are

thin, with an exaggerated elasticity; its internal surface is reticulated and shows fatty degeneration. The intercostals, instead of being parallel, come off irregularly. The condition of the heart is variable. In a certain number of cases it is dilated and hypertrophied, in others it is small, with or without dilatation of the right ventricle, and the endocardium is thin and transparent. The dilatation and hypertrophy of the heart are a consequence of the narrowness of the aorta; the smallness of the latter is the result of a general vascular hypoplasia.

Chlorosis may, however, appear independently of the arrest of development of the vascular system; moreover, these defects may be sometimes demonstrated without a symptom of chlorosis. Especially is this latter true in young tuberculous patients, in whom genital infantilism and even narrowness of the aorta are not rare.

At the author's suggestion M. Jolly had studied chlorotics in relation to tuberculosis. Out of fifty-four cases, in twenty-five the father or mother of the patient had died of this disease; in seven the grandparents, the uncles, aunts, brothers, or sisters were affected; and in eight the patients themselves showed indisputable signs of tuberculosis.

Dr. Sansom, of London, said he agreed with Virchow that in many cases chlorosis depends upon an imperfect development of the aorta whereby this vessel is comparatively small. But he had observed that the smallness of the aorta depended often on the smallness of the pulmonary artery. He had seen a case of profound anæmia without cyanosis in an infant in whom he found extreme smallness of the pulmonary artery. In many other cases all the signs of stenosis of the pulmonary artery were present, but eventually by treatment all these signs disappeared. This shows the importance of treatment in such cases—exercises, baths, etc., directed to the increase of the capacity of the lungs, of course accompanied by medicinal treatment and the use of the salts of iron and arsenic.

Dr. Ewald, of Berlin, said that at present the theory of vascular hypoplasia appealed most to him and he believed that in the near future it would be placed on a solid basis.

Dr. Gilbert ended by saying that he was very much pleased to find his theory defended by Professor Ewald. In relation to what Professor Sansom had said, he wished to repeat that while he believed vascular hypoplasia to be usually the cause of chlorosis, it was not an absolutely constant one.

Morphology of the Blood in Leukæmia.—Dr. Dock, of Ann Arbor, reported a case of chronic leukæmia with an increase of only small mononuclear cells in the blood, in which the period of time during which the blood was examined and the opportunity for examining the tissues post mortem seemed to furnish important data for the study of leukæmia. The patient was a man fifty-two years old. When forty-eight years old he had influenza, from which he never entirely recovered, but remained pale and weak. Two years later he discovered a tumor in the left side. This grew larger slowly, causing after a time marked dyspnœa. The speaker saw the patient one and one-half years after he discovered the tumor. He was pale, dyspnœic, and had slight œdema of the ankles. The spleen and liver were much enlarged, the former reaching from the eighth rib in the axillary line to the middle of the left rectus muscle and the iliac fossa; the liver extended to the level of the navel. The lymphatic glands of the axilla and inguinal region were slightly enlarged. He complained of pain in the sternum, in some of the ribs, and in the tibiæ. The blood was pale and watery. Examination showed red blood cells 1,925,000, leucocytes 312,500, hæmoglobin, by Fleischl's method, forty per cent. Almost all of the leucocytes were of the size and appearance of small lymphocytes, rarely exceeding the diameter of the average red cells. The multinuclear cells were decreased in number. Eosinophiles were present in the proportion of one to one thousand, sometimes only one to three thousand. Leucocytes with round or oval nuclei and coarse neutrophile granulations were present in proportion of one to five per thousand. Nucleated red cells—normoblasts—were present in proportion of about one per thousand. The blood always contained large numbers of degenerated leucocytes recognizable only in stained preparations. It is possible many of these were overlooked in the counts of fresh blood. The patient died four months after the speaker had first seen him, of influenza with broncho-pneumonia. In the last illness the condition of the blood remained unaltered. Charcot's crystals were never found. The coagulability of the blood was diminished. Just before the influenza the blood examination showed red blood cells 1,542,000, white cells 580,000, hæmoglobin, by Fleischl's method, thirty per cent. The histological changes in the various organs were found to consist essentially in a marked increase or new growth of lymphoid tissue. The following were Dr. Dock's conclusions: (1) The peculiarities of leukæmic blood depend on the kind rather than the seat of the alterations; (2) The excess of cells may be derived from any tissue in which they are formed, provided means are present for entering the circulation: (3) In leukæmia the blood may be characterized either by a polymorphism of leucocytes or by a marked preponderance of one particular kind of cell, especially of cells having the general appearance of lymphocytes, but at present these cells should not be described as lymphocytes, without details of their exact peculiarities, especially their tinctorial peculiarities.

The Hæmatokrit.—Dr. Daland, of Philadelphia, demonstrated the hæmatokrit with a number of important and practical modifications. These were new capillary tubes, upon which had been placed a scale and a lens front, by the aid of which the column of red blood corpuscles could be easily and accurately read. He also gave a careful and detailed description of a new technique by which the entire study of the blood may be completed within three or four minutes.

The Blood Test of Diabetes by Means of Aniline Dyes.—Dr. Ludwig Bremer, of St. Louis, read a paper in which he described the following simplification of his method of diagnosing diabetes from the blood: Spread a drop of blood obtained from the finger tip of a diabetic of a glass slide, by means of another slide; the film must be rather thick. Spreading in a wavelike fashion is preferable. Make a number of such preparations, say ten, and an equal number of preparations of non-diabetic blood for the purpose of control. Place them in a metal oven, the tray on which they rest being at least six inches from the bottom of the heating apparatus. The thermometer must be so adjusted that the bulb rests on the tray. Turn on the flame and let the heat run up to about 135° C., which is the best temperature for the test, although a few degrees either way do not make much difference. The time to be consumed in heating, until the desired degree is reached, is from six to ten minutes. The apparatus is allowed to cool, until the preparations can be handled conveniently. Now prepare a one-per-cent. aqueous solution of Congo red, in a Naples tube or any other similar kind of glass jar. Place two specimens, one of diabetic, the other of non-diabetic blood, back to back, in the reagent. After one and a half or two minutes rinse in water, when it will be found that the non-diabetic blood has assumed the pronounced Congo-red stain, whereas the diabetic has proved refractory or is only slightly stained, not red, but orange. Methyl blue (not meth-

ylene blue) gives equally satisfactory results. Biebrich scarlet stains the diabetic, but not the non-diabetic blood film. There are many other dyes which show a differential behavior toward diabetic and non-diabetic blood. The essential of success is the obtaining of the proper temperature. The specimens may remain in the reagent longer than two minutes, say five or ten, but if retained too long the selective principle determining the reaction is drawn out, and both preparations are stained alike.

The constituent of the blood determining the positive or negative stain is the red blood corpuscles. They are in an abnormal state in diabetes, which is calculated to render some of the diabetic phenomena intelligible. Contrary to Lépine and Lyonnet, who have experimented with the older method recommended by the author, the latter holds that the reaction is not one merely of greater or lesser alkalinity. There exists a peculiar state of the hæmoglobin, in consequence of which the oxygen carriers are hampered in their functions. The test lends color to the opinion expressed by Spitzer, that the glycolytic ferment is contained in the red blood corpuscles. Lépine and Lyonnet have also claimed that leukæmia showed the same color reaction. This is true of overheated specimens. If the details of the test recommended by the speaker are strictly adhered to, leukæmic blood behaves like non-diabetic blood. Maric and Le Goff, of Paris, have verified Bremer's experiments and repeated them before the Société des Hôpitaux. Dr. Bremer claimed that even in diabetics whose urine is temporarily free from sugar his blood-test holds good and proves the existence of the disease. Even in the prediabetic stage, a disturbed taste of the metabolic equilibrium is revealed by the test. In addition to the well-known experimental phlorrhidzin diabetes, Dr. Bremer said that there exists also a phloroglucin diabetes. The former is kidney diabetes, the latter blood diabetes.

Diabetes Mellitus.—Dr. William Pavy, of London, read a paper on this subject which was one, he said, that had hitherto puzzled all investigators, but modern research has cleared up the difficulties; diabetes mellitus is no longer the intricate disease of formerly and we can look at it now in a sensible light. Diabetes mellitus consists in a malassimilation by the animal organism of the carbohydrates of the food. Ordinarily the carbohydrates, when properly neutralized, go to benefit the system, but in diabetes instead of benefiting they simply pass through as waste products. The province of the physician is to investigate the nature of the error which causes this, and then bring back to the system its natural powers. The first serious fault is in the villi of the small intestine. Under normal conditions of health, they so change the carbohydrates that little or no sugar as such gets into the portal vein, and so our first step in the treatment of diabetes is to prevent the carbohydrates from passing unchanged into the portal vein. In order that sugar may appear in the urine it must have been in the general circulation, and so if we prevent it from reaching the general circulation we shall stop its elimination by the urine. It is absolutely true that under conditions of health there is no sugar in the general circulation, for if we inject sugar into the vein of any individual, just so much as has been injected will later be found in the urine. It was formerly said that the carbohydrates as such went to the muscles to make heat, but this we can demonstrate to be false and we can say with certainty that the carbohydrates, whether under the form of glucose, maltose, or starch, getting into the general circulation cannot be used by the organism and so are eliminated as waste. Between the intestines and the liver the carbohydrates must all be converted into principles which the general circulation can distribute, and the speaker believed that most of this conversion takes place in the intestine itself. That carbohydrates are changed into fat there is no doubt, since we can find almost as much fat in the lacteals after the ingestion of carbohydrates as after that of fatty food. Consequently when we find sugar in the urine, we appreciate at once that the power in the intestine of proper assimilation has been weakened. In a perfect condition this power is such that even excesses do not disturb it, but we can easily imagine an individual whose power of assimilation is just so balanced that when he eats normally there is no trouble, but a banquet or the ingestion of an excess of carbohydrates for any reason will precipitate some of them into the general circulation and they will consequently appear in the urine. Such a man may go to Dr. A., who, finding sugar, will tell him he has diabetes, and later to Dr. B., who will contradict the first. This has happened more than once and is to be remembered. But in actual diabetes the condition is much worse; the power of assimilation of starches may be almost entirely gone. When this is so the patient rapidly loses flesh and strength, since carbohydrates are necessary for the animal organism.

The indications for treatment are evident, and in the majority of cases the assimilative powers can be brought back, if not to the normal, at least to a condition approaching it. The first indication is to prevent the sugar from getting into the urine. Keep it from the intestine, and this is easy; therefore, stop the carbohydrates for a time, limiting the patient to other foods. At once on limited diet the sugar in the urine lessens, after a time it stops, and still later the gradually increasing ingestion of carbohydrates will have the effect. For the present we can say only that then intestine is at fault, but Dr. Pavy could not help thinking we shall later find it to be a nervous condition acting on the vessels of the intestine.

Dr. Bremen, of St. Louis, said that he had listened with much pleasure to this paper and he desired to call attention again to his discovery. He claimed that his test with the aniline colors showed the red corpuscles to be at fault, and he believed that the red corpuscles normally contain a glycolytic ferment.

Dr. Hughes, of St. Louis, said that through the labors of the eminent men of to-day diabetes was not the terror it was years ago, and he was very glad to be present to hear Dr. Pavy say, he believed for the first time, that diabetes was probably due to a nervous condition.

Cessation of Respiration before that of Circulation.—Sir Dyce Duckworth, of London, reported briefly four cases, three of cerebral or cerebellar abscess consecutive to otitis media suppurativa and one of cerebral hemorrhage from tumor, in which the patient absolutely ceased to breathe for periods varying from three to five hours before the action of the heart was arrested. Artificial respiration was of no avail in restoring the lost function and hypodermic injections of strychnine and ether were equally powerless to re-establish it. Experiments were quoted to show that this occurrence has been noted in cases of injury to the brain from gunshot wounds, and the author discussed the possible explanation of this peculiar condition.

Fifth Day—Wednesday, August 25th.

The Relation of Nervous Dyspepsia to General Nervous Disturbances.—Dr. Rosenheim, of Berlin, read a paper on this subject. He defined nervous dyspepsia as a sensory neurosis differing from hyperæsthesia in that the disturbances are intimately associated with digestive activity of the stomach and that the symptoms are very similar to those of different

forms of gastritis. In nervous dyspepsia both motor and sensory functions may be disturbed. There may be an acidity, subacidity, or hyperacidity. Diminution in the amount of the gastric juice, hypermotility, and atony are often found. If the functional disturbance is marked and continues a long time, nervous dyspepsia may be easily confounded with other affections, especially with one or other of the forms of gastritis. Nervous dyspepsia, thus defined, is not the frequent affection it is commonly supposed to be and not all dyspeptic symptoms in a nervous individual point to nervous dyspepsia. In fifty such cases, post-mortem examination revealed the fact that more than one-half of the patients had suffered from other diseases of the stomach, principally inflammatory processes, and only in eleven cases were the complex symptoms of nervous dyspepsia found.

Nervous dyspepsia usually brings with it other nervous symptoms, sometimes giving us a complete picture of neurasthenia or (more seldom) of hysteria. That nervous dyspepsia is always a symptom of neurasthenia has been maintained, and it often happens that nervous symptoms depend on stomach disturbances and disappear when the latter are cured. Nevertheless, in nervous dyspepsia the treatment of the stomach symptoms is very useful, especially when combined with the treatment of the general condition and the pathogenesis.

Neuropathic Dyspepsia and its Relations to Changes in the Rhythm of the Heart.—Dr. Sansom, of London, read a paper with this title. He said he had made a clinical study of a considerable number of cases in which there were disturbances of the rhythmic action of the heart, in order to determine if there was an association between it and dyspepsia. The conclusions arrived at from this study were the following: 1. In the essential tachycardias without complications the manifestations of dyspepsia are not marked. In forty-six cases there was not one of dyspepsia which persisted. 2. In the cases of tachycardia following influenza dyspepsia was much more frequent, five out of thirty-seven cases. 3. Tachycardia accompanied by exophthalmic goitre was often associated with serious dyspepsia. 4. Arrhythmia of the heart without organic complications was often associated with dyspepsia. 5. Persistent brachycardia was evidently associated with marked dyspepsia, but intermittent brachycardia was also accompanied by epigastric pains, vomiting, and other signs of dyspepsia.

The Dress of Woman and the Position of Her Stomach.—Dr. Bendersky, of Kieff, read a paper in which he described a new sign which he had found to be an aid in defining the position of the stomach. The corset is well known to be injurious, but it is not the corset alone that is the whole cause. The lower part of the corset may even be useful, by protecting the stomach from injury by the petticoats, etc., for if the skirts are fastened tightly without a corset much more harm is done on account of the linear constriction. With the stomach in the normal position, the waistband of the dress lies between the stomach and transverse colon, but if there is gastroptosis the lines of the dress will not follow the greater curvature of the stomach (the author has seen such cases even in men) but lie above it. In looking at the female abdomen we see vertical and curved lines caused by the corset, but besides there is evident a horizontal line caused by the waistband of the dress. The author calls this line the gastric line because it defines the lower border of the stomach. It may also be found in men wearing tight waistbands.

Massage in the Treatment of Internal Diseases.—Dr. Dolega, of Leipzig, read a paper on this subject. He first reviewed briefly the history of treatment by massage. He showed that although many therapeutic discoveries had been made, massage still held its own high place. Moreover, many physicians who formerly were sceptical as to its usefulness, now ordered it, since physiological and experimental research had demonstrated its action and proved its worth. He gave the special indications for massage in the treatment of internal diseases; and said that mechano-therapy, especially massage, was destined to hold in the future even a still higher place in treatment and that the time had come when institutes of massage should be founded.

Gonorrhœal Endocarditis.—Dr. Thayer, of Baltimore, read a paper on this subject. The accumulating observations of recent years have demonstrated the fact that the pathogenesis of the different complications of gonorrhœa may vary materially in different instances. 1. That the complicating process may be of purely gonorrhœal origin has been shown particularly by the numerous cases of arthritis, occurring in connection with gonorrhœa in which the specific micro-organism has been demonstrated microscopically and obtained in pure cultures from the affected joints. 2. That complications may be due to a mixed or secondary infection with other pyogenic organisms has long been known, and the manner of development of such secondary processes has been well pictured by Finger in a recent article. 3. There is good reason to believe that serious focal lesions may occur in gonorrhœa without the actual presence of either the gonococcus or other micro-organisms, the lesions being due solely to the presence of circulating toxic substances. Definite proof of this hypothesis has not yet been advanced, but in view of the complete absence of bacteria on microscopical examination, as well as of the complete sterility of cultures taken from the affected regions in cases, for instance, of neuritis or myelitis secondary to gonorrhœa, as well as from analogy with other similar infectious processes, there is strong probability that such lesions exist. The presence of local foci of infection at remote points from the region originally affected, joints, tendon sheaths, etc., would lead us to infer that a true gonorrhœal septicæmia may occur. Everything points to the blood as the means by which the organisms are transferred to distant points. This was practically proved when Dr. Blumer and the speaker succeeded for the first time in obtaining the gonococcus in pure culture during life from the circulating blood of a case of ulcerative endocarditis. The case was then detailed. The blood was taken from the median basilic vein with a sterilized syringe and mixed with melted agar which was immediately plated. The first culture was negative, but the second and third showed minute white colonies representing apparently a pure culture of small biscuit-shaped diplococci which failed to grow on transmission to agar-agar, gelatin, potato, bouillon, and litmus milk. The autopsy confirmed the diagnosis, revealing an extensive ulcerative endocarditis of the mitral valve. In the thrombi upon the valve were found large numbers of small oval diplococci having all the morphological and tinctorial characteristics of gonococci. In this case the gonorrhœa was not recognized during life, but in a second case the gonorrhœa was recognized and every precaution was taken to make the bacteriological examination of the blood without question. In this case (that of a boy aged nineteen) two cubic centimetres of blood were drawn from the median basilic vein and mixed with four cubic centimetres of nutrient agar and plated. At the end of forty-eight hours numerous colonies half the size of a pinhead, granular in appearance with somewhat irregular borders, were found. They were of biscuit or kidney shape, the flattened sides of the cocci being turned toward each other, forming pairs.

They stained well with the ordinary basic stains and decolorized by Gram's method. Transplanted to human blood-serum agar by a smear upon the surface, there developed a fair number of colonies similar to the above and made up of diplococci having the same morphology and tinctorial reactions. Transplanted to ordinary agar there resulted a growth of a very few fine colonies made up of the same diplococci. On gelatin, ox-blood serum, and bouillon there was no growth. At the end of eighteen days cocci had all died out on the orginal plates. Later two cultures were made that acted in the same way. The autopsy showed the tricuspid valve to be the seat of an extensive thrombus formation. (The speaker showed an admirably executed painting of this thrombus.) Bacteriological examination of this thrombus also showed gonococci in pure culture. The gonorrhœal nature of the endocarditis as well as the actual existence of a gonorrhœal septicæmia seemed to be demonstrated beyond a doubt by the discovery and reproduction of the gonococcus in pure culture from the circulating blood during life and after death from the affected cardiac valves and from the pleural and pericardial exudates.

Trial of the Electrical Synthesis of Franklinization and of Currents of High Frequence.—Dr. Apostoli, of Paris, read a paper on this subject. The speaker's conclusions were: 1. No form of electricity can be constantly and absolutely the best in every case, since each form preserves its therapeutic usefulness under proper circumstances. 2. The symptomatic reactions of one or the other form may be useful in electro-diagnosis, and they show us the therapeutic inclinations better.

So-Called Hypertrophic Pulmonary Osteo-Arthropathy of Pierre Marie, without Pulmonary Disease.—Dr. John Lindsay Steven, of Glasgow, described a case of peculiar enlargement of the hands and feet due to a subperiosteal new formation of bone in the affected parts, which had all the clinical characters of the affection which Marie has designated hypertrophic pulmonary osteo-arthropathy. The paper was illustrated by photographs and skiagrams which showed very well the peculiar deformity, the skiagram in particular demonstrating the nature of the bone affection. The patient was a laborer, aged forty-eight, who had been ill in all about a year before his admission to Dr. Lindsay Steven's wards. He first noticed enlargement of the hands and feet, at first painless, but latterly disabling him on account of pain and stiffness in the ankles and knees. About four months before his admission he had a cough which, however, never laid him aside from work, and which had entirely gone fully a month before his admission to the infirmary. There was absolutely no sign of cardiac or pulmonary disease. The hands were greatly thickened, especially the fingers—the nails also were so curved that the point of the finger was covered by nail and not by skin. The lower end of the forearm bones were greatly thickened and rough, the roughness being traceable half-way up the arm. This was well demonstrated by the Roentgen rays. Sensation was normal everywhere. Vision was slightly defective, and the temporal half-field was slightly diminished. There was no kyphosis, no retrosternal dulness, no prognathism, or mental defect. The quantity of urine was excessive, averaging ninety ounces daily, but not otherwise abnormal. The ankles and feet presented characters on the whole similar to those observed in the upper extremities. The trunk and chest as regards their form were normal. Treatment had been unavailing.

The interest of the case was that we had all the clinical features of Marie's cumbrously named pulmonary hypertrophic osteo-arthropathy without the pulmonary disease, which in this case could not have been caused by reason of the non-absorption of pulmonary toxins. Its relationships to acromegaly and to Paget's osteitis deformans were also considered, but Dr. Lindsay Steven did not think that the clinical features corresponded to those of either of these affections. On the whole, he was inclined to regard the peculiar deformity as essentially rheumatic in nature.

Several papers were then read by title, after which the section was adjourned.

AMERICAN ASSOCIATION OF OBSTETRICIANS AND GYNECOLOGISTS.

Tenth Annual Meeting, Held at Niagara Falls, New York, August 17, 18, 19, and 20, 1897.

First Day—Tuesday, August 17th.

The association met at the Cataract House, under the presidency of Dr. James F. W. Ross, of Toronto.

An address of welcome was delivered by Dr. W. R. Campbell, of Niagara Falls, which was responded to by The President.

Puerperal Eclampsia with Special Reference to Treatment.—Dr. William Warren Potter, of Buffalo, read the first paper. The principal object of the paper was to advocate principles which the speaker grouped under the following heads: 1. Though the pathogenesis of eclampsia is unsettled, it belongs solely to the pregnant or puerperal state. It is not apoplectic, epileptic, or hysterical in character. 2. It depends upon toxæmia due to overproduction of toxins and underelimination by the emunctories. 3. These toxins probably have their origin in the ingesta, in intestinal putrefaction, in fœtal metabolism, one or all, and there is coexisting sluggishness, impairment, or suspension of elimination. 4. When the prodromes of eclampsia appear, the kidney should be interrogated as to its functions and all symptoms carefully watched. 5. Treatment is preventive and curative. Preventive treatment is medicinal and hygienic; curative treatment is medicinal and obstetric. 6. Milk diet and distilled water should be given in the pre-eclampsic state to dilute the poison, hasten its elimination, and nourish the patient. 7. Bloodletting should be employed only in plethora or cyanosis. It is liable to cause anæmia if persisted in or repeated, whereas red blood corpuscles must be conserved, not wasted. Glonoin diminishes vasomotor spasm, hence may be given freely in appropriate cases. Veratrum viride is a cardiac depressant and a dangerous remedy if pushed to an extent that will control convulsions. 8. Eclampsia is the expression of a further maternal intolerance of the fœtus; hence as a prime measure the uterus should be speedily emptied of its contents. 9. Medicinal treatment alone is delusive, and when relied upon exclusively is fraught with danger to both mother and fœtus; whereas in the prompt induction of labor is found a rational application of science to a desperate condition. 10. Finally, induced labor furnishes, in the present state of our knowledge, the only basis of expectation for a diminished mortality in a toxæmic disease of high death rate.

Puerperal Diphtheria.—Dr. H. W. Longyear, of Detroit, read a paper on this subject, the object of which was to bring before the profession the fact that the Klebs-Loeffler bacillus is a potent factor in the etiology of puerperal infection, six cases being reported in proof of the position of the writer. The diphtheritic character of each case was determined not only by clinical evidence, but by bacteriological examination, made by the bacteriologist of the Detroit board of

health. Five of the patients recovered and one died, the one death occurring in the only case in which antidiphtheritic serum was not used.

The Source of Puerperal Sepsis.—Dr. John M. Duff, of Pittsburg, said that the exact source of puerperal sepsis in any given case was not always easy to determine. In a large proportion of cases, however, a careful inquiry would be rewarded with the revelation of a source. When found, it generally proved to be one which could have been avoided. Aseptic midwifery had done much to prevent puerperal sepsis, and consequently to lower the rate of mortality following childbirth. He had heard the opinion expressed that the accoucheur who was so unfortunate as to have a case of puerperal sepsis was guilty of malpractice. Such expressions he thought were extravagant and were not warranted by our present knowledge and experience. Sepsis does occur sometimes, despite the best efforts of the practitioner to prevent it. While he believed that puerperal sepsis cannot always be prevented, he did believe that with ideal surroundings, with a careful and skilful physician, assisted by an educated and conscientious nurse, the number of cases could be reduced to a minimum. Frequently too much reliance was placed upon antiseptics. For instance, a well-known member of the profession had said in his hearing a short time since that he felt perfectly safe in attending a case of labor after waiting upon a case of erysipelas or diphtheria, if he washed his hands well in a strong bichloride solution. Dr. Duff thought the patients would be safer if he went to them under such circumstances with fear and trembling, which would cause him to perform further ablutions, if possible.

Toxæmia of Pregnancy.—Dr. Adam H. Wright, of Toronto, read a paper in which he said that the chief symptoms of this condition were salivation; disorders of digestion, with sometimes a peculiar taste and constipation; general malaise, anæmia, nervous disturbances or headache, disorders of vision, irritability, deficient excretion of urine or some of its constituents, and albuminuria. To speak briefly, he thought any sign of the slightest departure from ordinary health during pregnancy should make us suspect the advent of general toxæmia, and should receive careful investigation and thorough treatment. If, for instance, there were general malaise with slight headache, but no albumin in the urine, we should not be deceived, since albuminuria was only one of the symptoms of systemic poisoning, and sometimes the last to appear. Its absence proved absolutely nothing. Coming to the treatment, reference was made to milk diet for toxæmia of pregnancy. He believed that a purely milk diet is good for young babes and calves, but he did not think that it is suitable for adult human beings. Yeo, in his admirable book on "Food in Health and Disease," shows clearly that milk is not a suitable food for healthy adults, because it contains an excess of albuminates and fats, and that it should be mixed with other foods, especially the carbohydrates. If it be conceded that milk alone is not the best food for healthy adults, it is difficult to conceive how it can be the most suitable in any case of disease.

The Treatment of Puerperal Endometritis by the Carossa Method.—Dr. Edward J. Ill, of Newark, N. J., read a paper with this title. There appeared, early in the winter of 1896, a pamphlet by K. Carossa, describing a method which consists simply in the use of alcohol as an irrigating material, supplemented by gauze packing of the uterus in such a way that the alcohol may find its way into the most distant recesses of the uterus. A catheter is introduced into the uterus, and this organ is filled with absorbent gauze. At the external end of this catheter a funnel is attached, through which a twenty to twenty-five volume per cent. alcohol solution is poured so as to flow into the gauze with which the uterus is filled. The quantity to be used is from thirty to fifty cubic centimetres every hour, day and night. In from three to six days the gauze is removed. The originator of this method had some fantastic theory of the evaporation of alcohol, with which the author of the paper could not agree. Dr. Ill has used the above method, slightly modified, with good results, and recommends it for further trial, especially so on account of its great simplicity.

Sequelæ Following Supravaginal Hysterectomy.—Dr. Rufus B. Hall, of Cincinnati, read this paper. He said he thought the profession had been too hasty in approving the present methods. It had taken the stand that there was nothing more to be desired—the operation was complete. While the doctor had no new method to offer, he hoped the discussion of his paper would suggest something to improve the technique of the present methods. He referred to objections to the extraperitoneal method, and then spoke more in detail of total extirpation. He was one of the first to advocate and make this operation, and he had attained excellent results with it. However, it did not meet his ideas of a perfect operation. The final results were good, but there was a primary difficulty that was disagreeable. Suppuration about the ligatures necessarily took place on the sixth or seventh day, causing a slight rise in temperature. To overcome the suppuration, he used specially prepared catgut for the ligatures below the peritoneum. He found the catgut unreliable on account of the danger from hemorrhage through slipping of the knots, and so abandoned its use. The doctor closed his paper by saying that in spite of the fault he had to find with total extirpation, he preferred it to supravaginal hysterectomy as practised by Baer and modified by others. He felt more certain of his final results with the former method.

The Sequelæ of Dead Ligatures and Sutures.—Dr. George M. Hughes, of Philadelphia, read a paper with this title. While assisting Dr. Joseph Price in his abdominal work, he had recently been greatly interested in a number of cases in which he reopened the abdomen for the freeing of adhesions and the removal of dead ligatures and sutures. Sutures and ligatures should be of that material which is most easily sterilized and which combines great strength in a small bulk. It was always preferable to use a material capable of being rendered aseptic by heat or boiling. If this could be done, we could at all times have the means at hand to render perfectly sterile our ligatures. For this purpose he finds that for pedicle ligatures and for bowel work the twisted Chinese silk is the best, of finest quality and sufficiently small to secure safe tying; for closure of the abdominal incision, silkworm gut and the through-and-through method. What becomes of the ligatures? If small and sterile, they become encapsulated and are rapidly absorbed. If plaited ligatures and large hawsers are used, whether infected or not, they are never absorbed, but their presence as foreign bodies gives a train of symptoms unbearable in their distress and constant in their duration. The same conditions are found about the pedicles, only here we have adhesions of omentum, large and small bowel, and bladder to both pedicles. To obviate postoperative accidents, we should select that method of applying ligatures which gives safety with the least quantity of material. For pedicles the simple figure-of-eight tie is the best, in that it gives a firm, small, strong tie, and one not liable to slip. The pedicle is then cut cone shape. The pedicle must be made as small as possible; large pedicles are prone to behave badly, and to this are due the postoperative adhesions of omentum, bowel, or bladder.

Second Day—Wednesday, August 18th.

Postclimacteric Conditions that Simulate Advanced Uterine Cancer.—Dr. M. Rosenwasser, of Cleveland, Ohio, read a paper on this subject. The writer commended the teaching that irregular hemorrhages and sero-sanguinous discharges, whether occurring during the parturient age or long after the menopause, are good and sufficient reasons to suspect malignancy. We carefully watch for early symptoms, and by their detection occasionally succeed in removing the disease while it is still local. On the other hand, we sometimes are caught off our guard when confronted by postclimacteric cases presenting all the classical characteristics of advanced malignant disease. The text-books are deficient in not sounding a note of warning against possible errors in the late stages. The so-called classical symptoms may be due to other (not malignant) conditions of the genital tract. Owing to effacement of the vaginal portion of the cervix in old age, the differential diagnosis is in most cases limited to corporeal diseases of the uterus. Before the diagnosis of corporeal cancer can be made, other diseases must be excluded. The conditions which are likely to simulate advanced cancer are the following: 1, Senile vaginitis; 2, foreign bodies in the vagina; 3, gangrenous fibroids; 4, atrophic, senile, or postclimacteric endometritis; 5, postclimacteric pyometra. Of these conditions, the last is especially liable to lead to errors. In conclusion, the author called attention to the singular fact that in the presence of the essential predisposing conditions—age, low vitality, cicatricial tissue, adhesions, chronic inflammation, and irritating discharges—cases of transformation into malignant disease are either unknown or exceedingly rare.

Certain Cysts of the Abdominal Wall.—Dr. Richard Douglas, of Nashville, Tenn., followed with a contribution on this subject. He confined himself to a consideration of abnormalities of the urachus, and reported an interesting case of urachal cyst which occurred in a woman, thirty-six years of age, married eleven years, and sterile.

Conservation of the Ovary.—Dr. B. Sherwood Dunn, of Los Angeles, Cal., read a paper on this subject. He said that Brown-Séquard believed and taught as a principle of physiology that every gland, whether provided or not with excretory ducts, gives to the blood a certain useful principle, the absence of which is felt and made apparent after destruction or modification of the functional activity of the gland by disease. In observations made upon 100 cases operated upon in Broca and St. Louis hospitals in Paris, he found that when women had prematurely lost both ovaries 78 per cent. subsequently suffered a notable loss of memory; 60 per cent. were troubled with flashes of heat and vertigo; 50 per cent. confessed to a change in their character, having become more irritable, less patient, and some so changed as to give way to violent and irrepressible fits of temper; 42 per cent. suffered more or less from mental depression, and 10 per cent. were so depressed as to verge upon melancholia. In 75 per cent. there was a diminution in sexual desire, and some of these claimed they experienced no sexual pleasure; 13 per cent. were not relieved of the pain from which they suffered; 35 per cent. increased in weight, and some became abnormally fat. Some complained of a diminution in the power of vision; 12 per cent. noted a change in the tone of their voice to a heavier, more masculine quality. Some 15 per cent. suffered from irregular attacks of minor skin affection; 25 per cent. had severe headaches, as a rule increased in intensity at the menstrual period. Equally as many complained of nightmare, more or less consant, while about 5 per cent. suffered from insomnia. In a few cases there existed a sexual hyperexcitability not present prior to the castration. He particularly noted a few cases presenting gastric reflexes, in which without any premonitory symptoms or apparent cause the stomach would reject food or refuse to prepare it for intestinal digestion, and the consequent distress following the fermentation compelled the patient to seek relief. It should be noted that usually these troubles were more marked in women under thirty or thirty-three years of age. He had for some time been favorably disposed to the hypothesis advanced by Brown-Séquard, and any scepticism that he might have entertained of the theory of ovarian secretion and its usefulness and necessity to the equipoise of the whole system had been completely dissipated by the results of experiments made with ovarian substance in patients who had lost both ovaries or were suffering from troubles which in a greater or less measure were due to a diseased condition of the ovary.

Some Observations upon Ventral Fixation.—Dr. Herman E. Hayd, of Buffalo, in a paper on this subject, stated that ventral fixation or suspension of the uterus, coupled with the various plastic operations upon the cervix and vagina, was the only means surgical or anatomical which will fix and support for future comfort and well-being an extremely prolapsed uterus. In his last six cases of ventral fixation, he sewed the uterus to the abdominal wall with chromicized catgut, No. 3, and did not even scarify the peritoneal covering of the uterus. He held the organ by thin sutures, which took in simply the peritoneum and the connective tissue over it; but in one case in which the organ was very heavy and the woman short and stout, he hitched on to the rectal fascia and muscles. He has invariably sewed the anterior surface of the uterus, feeling more satisfied with the position assumed under these circumstances than when the sutures catch the superior and posterior surface, as is advocated in ventral suspension. In patients he has operated on and those he has examined after operation of ventral suspension, he has found the organ in a too anteflected position, and it may be the cause of some future annoyance. He has discarded silk and all unabsorbable ligature materials, believing that catgut can be sterilized and rendered absolutely safe and is perfectly manageable.

Surgery and Facts.—Dr. James F. W. Ross, of Toronto, then delivered the president's address. He said the work of members of the association was confined between the diaphragm, the perineum, and the abdominal walls, and that they had met to cultivate and promote a knowledge of whatever relates to abdominal surgery, obstetrics, and gynæcology. Attention was drawn to some unsettled questions, the first being peritonitis. Are we able to do more to save the lives of patients suffering from this disease in its acute form than we were ten years ago? Are we not but little better off, with all our antiseptic and aseptic washes, gauze and tube drains, and purgatives? He was satisfied that surgery could carry us no farther when battling with this disease. The questions of operating upon the appendix and the diagnosis and treatment of ectopic gestation had been fairly well settled. The method of dealing with the pedicle in ovariotomy had been settled, except for the fact that some operators preferred silk, while others were assured of the safety of catgut. Operations upon the gall bladder and gall ducts had been performed many times during the past ten years, and they were now well recognized as proper surgical procedures. The operations of nephrectomy and nephrotomy were looked upon as every-day procedures, justified by the consensus of surgical opinion. Abdominal hysterectomy was an operation that had been much improved and simplified, some operators being still wedded to

the clamp, while others preferred some of the other methods. The advisability of oöphorectomy for some fibroids could not be doubted. There were two operations that Dr. Ross thought were of doubtful value, namely, the fastening of the kidney to the side, and the fastening of a uterus anywhere. He considered that these operations had been recklessly performed and unnecessarily undertaken. Certain operations to which more thought must be given are those for intra-abdominal and intrapelvic cancer. When peritoneal cancer has been diagnosed, surely exploratory operation is uncalled for. Operations for other forms of cancer are of questionable utility. Take, for instance, resection of a cancerous intestine, gastro-enterostomy for pyloric cancer, and removal of the uterus for uterine cancer. Gastro-enterostomy and resection of the intestine are poor makeshifts. For carcinoma uteri, vaginal hysterectomy is the only operation that should be contemplated, but at best it prolongs life for but a short time.

Treatment of Uterine Displacements.—Dr. C. C. Frederick, of Buffalo, N. Y., read a paper entitled "Which is the Preferable Operative Method of Holding the Uterus in Position?" All retroversions do not produce symptoms, but a certain proportion is accompanied by hypertrophy of the uterus, endometritis, leucorrhœa, pain, backache, menorrhagia, metrorrhagia, or general malaise. Constitutional treatment fails to relieve a large proportion of them without restoration of the uterus to a normal position and a cure of the accompanying hypertrophy and endometritis by reposition. The large factors in the continuance of the ill effect of retroversion are torsion of vessels, infection of the endometrium, and defective drainage of the uterine cavity. Retroversion is a first stage of prolapse, and the uterus ought for that reason alone to be replaced and held in position. Sterility is one frequent result of retroversion. Results of treatment are good by operation or by holding the uterus in position by a pessary, if possible together with general tonic treatment, Weir Mitchell rest treatment, etc. Many patients are cured and eventually get strong and well again. Ventrofixation has been discontinued by the writer in women liable to bear children. He uses it only to hold up the uterus in operations for prolapse and in those cases in which he has removed both tubes and desires to hold the uterus in position, time being an element in the operation. The writer has seen no ill results during labor, and knows of none occurring in his own patients, although several have borne children. He had seen no recurrence of retroversion, even in those who have borne children. His preference was for the Alexander operation or some of its modifications, in cases of women who have borne children and when there are no adhesions or disease of the adnexa. Women who have never been pregnant are liable to have poorly developed round ligaments, prone to tear away from the anchoring sutures. In these he opened the abdomen and shortened the round ligaments by one of the methods devised by Mann, Dudley, or Wylie. He gave Mann's method the preference. Several of the patients have borne children both after the internal and external shortening of the round ligaments, with good results. The writer used unabsorbable ligatures or sutures, always employing plain catgut or chromicized catgut when a suture is used for a long period. He never had used any of the vaginal methods of fixation, not being pleased with them.

Third Day—Thursday, August 19th.

The Technique of the Dry Method was the title of a paper by Dr. Edwin Walker, of Evansville, Ind., in which he said that by the dry method is meant a technique in which no water or other fluid is used. This does not apply to the preparation before the operation. After the first stroke of the knife until the wound is closed, not a drop of water is used. The writer has employed it exclusively for several years with good results. The technique is as follows: Nurses are instructed to use every precaution to prevent soiling the hands in septic cases, and thoroughly to disinfect the hands after any suspicion of contamination. Every instrument used is sterilized before it is put away. The hands are scrubbed thoroughly with a brush, with liquid soap (equal parts of green soap, glycerin, and alcohol), and repeatedly rinsed in sterile water. They are then wiped off with alcohol, dipped for two minutes in bichloride solution, 1 to 1,000, and then washed off with salt solution. The field of operation is similarly prepared, except that the scrubbing is repeated daily for two or three days before the operation, and a soap poultice used at night. The instruments are boiled in soda solution for five or ten minutes, wrapped in towels, or placed in metal boxes, which are opened only at the time of operation. Plain gauze is used for every purpose except packing the uterus, and in rare instances when drainage is used iodoform gauze is preferred. The silk ligatures are wrapped on spools and placed in glass boxes, and the silkworm gut and silver wire in long glass tubes, and all sterilized by steam, as are the dressings. The plain catgut is boiled in alcohol, and the chromicized is prepared after Edebohls' method. After the patient is placed on the table, the dressing, which consists usually of plain gauze, is removed from the field of operation, and sterilized towels are adjusted as usual. The instruments are unwrapped and everything is in readiness. The sponges are used dry, and thrown away when soiled. The flat sponges in the abdomen are also used dry, and are provided with a cord which is clamped with a pincette. The latter is left outside, so that the sponge cannot be forgotten and left in the abdomen.

Surgical Shock and Hemorrhage. — Dr. Walter B. Chase, of Brooklyn, N. Y., read a paper, of which the following are the conclusions: 1. The treatment of shock should be preventive and curative, and to a large degree the indications for the former define the lines of treatment in the latter. 2. The proper exhibition of preventive measures includes a careful study of the functional activity and organic status of all important organs, and such treatment by hygienic, dietetic, and therapeutic measures as will elevate the standard of bodily and mental health to a degree in which the maximum power of resistance may be produced and maintained. 3. Special emphasis should be given to lithæmic and uræmic excretion, and to the condition of the circulatory and nervous systems. 4. Knowledge as to inherited power of resistance to and recovery from serious disease and accidents is of the highest value in determining the course of procedure and in estimating the chances for recovery after capital operations. 5. A supply of facilities and drugs for meeting all emergencies should be in constant readiness, with exact knowledge for the indications, dosage, physiological and therapeutic effect of special heart tonics and stimulants, including strychnine, digitalis, nitroglycerin, etc. 6. Limit the time of an operation to the shortest space compatible with thorough work and proper technique. 7. Save the patient to the utmost from the shock of fear, and in selected cases proceed to operation without informing the patient of your purpose. 8. In shock with hemorrhage supply the volume of venous and arterial loss by direct transfusion of decinormal salt solution into the patient's veins. 9. Bear in mind the influence position has on the circulation under both shock and hemorrhage, especially in anæmic conditions of the cerebro-spinal nerve centres and the heart.

Placenta Prævia.—Dr. W. H. Wenning, of Cincinnati, Ohio, read a paper on the treatment of this condition. The following is a summary of the treatment laid down by the author in the order of time of the accident, amount of hemorrhage, and condition of the patient: (*a*) Before labor: 1. Hemorrhage slight —rest, expectant treatment. 2. Hemorrhage moderate —tampon vagina. 3. Hemorrhage profuse—also try tampon and induce labor. (*b*) In the beginning of labor: 1. Hemorrhage moderate — Braxton Hicks' method, provided the obstetrician has skilled assistance at hand; otherwise tampon the cervix with the cervical bag, until (*c*) labor is well in progress, then rupture membranes and deliver by podalic version; or, if hemorrhage is arrested by the descending hand, deliver by forceps or permit spontaneous expulsion if pains are good. At any stage, when hemorrhage is excessive or cannot otherwise be arrested, manual dilatation, followed by *accouchement forcé*. The tampon is indicated: (1) In hemorrhage toward the end of pregnancy; (2) in the beginning of labor when the os is closed; (3) in moderate dilatation of the cervix, then use cervical tampon. It is contraindicated: (1) When dilatation is complete or nearly so; (2) when it fails to arrest hemorrhage even if dilatation is not far advanced. Rupture of the membranes is indicated: (1) When the os is well dilated and either spontaneous labor or artificial delivery may occur; (2) when by this method hemorrhage is better controlled than by other means; (3) when in the absence of labor pains it will be followed by immediate pressure of the presenting part. It is contraindicated: (1) When the os is undilated and pains are good; (2) in faulty presentation of the fœtus, unless it can be followed immediately by version. Version is indicated: (1) When the os will admit two fingers and combined version can readily be made, Braxton Hicks' method; (2) when the os is well dilated or dilatable and hemorrhage is profuse, direct or internal version; (3) in desperate cases, *accouchement forcé*. It is contraindicated: (1) When with a moderately dilated os combined version cannot be skilfully made (the cervical tampon); (2) when with a well-dilated os after rupture of the membranes the head immediately engages in the cervix.

Complete Hysterectomy after Injury during Parturition and Cæsarean Section. — Dr. Joseph H. Branham, of Baltimore, reported two cases and then discussed the causes and prominent symptoms of rupture of the uterus. When symptoms of uterine rupture occur, he said, delivery should be completed as rapidly as possible by the use of whatever means may best bring about the results. The child nearly always dies in a few minutes, so that only the mother should be considered. If the child has escaped into the abdominal cavity, immediate laparotomy is indicated. After the child has been delivered, two methods of procedure are recommended. One is the closing of the tear by packing with iodoform wicking and drainage of the parts with gauze. The other, which in complete ruptures is often more popular, is to do a laparotomy, cleansing the peritoneal cavity. In suitable cases the tear may be closed by the Sänger method. If the tears are very extensive and there is a strong probability of uterine infection, a Porro operation or complete hysterectomy is the best method. The preventive method consists in the early relief of difficult labor by suitable operative interference, instituted before the uterus has become very thin and damaged by long-continued pressure between the presenting part and the bones of the pelvis.

Tonic and Spasmodic Intestinal Contractions.—Dr. X. O. Werder, of Pittsburg, read a paper on this subject, in which he reviewed five cases—one by Dr. Murphy, two by Dr. Long, and two of his own—reported by Dr. Long at the Richmond, Va., meeting of the association, and added some additional cases of a similar condition that he had observed subsequently. He referred to cases reported by L. Heidenhain, and applied the term enterospasm, dividing the cases according to their nature and severity into spasmodic and tonic or tetanic forms. He thought that these cases are perversions of normal peristalsis, due to a reflex chemical or mechanical irritation exerted at the seat of contraction (either on the mucous or serous surfaces of the bowel) or elsewhere in the alimentary canal or abdomen. He said that they assume surgical importance when in the spasmodic varieties they simulate neoplasms—as in three cases of that variety reported—or when they cause obstruction to the fecal current, becoming true cases of dynamic ileus.

Dynamic Ileus Following Operations Involving the Abdominal Cavity, with Remarks on Adynamic Ileus.—This paper was read by Dr. Frederick Blume, of Allegheny, Pa. The author said that the differential diagnosis between post-operative intestinal obstruction and dynamic ileus is practically impossible, but that in either case the only chance for the patient is afforded by early operative interference. The surgeon, however, must distinguish these forms of ileus and a very obstinate form of constipation so often met with and so difficult to overcome, after operations in the abdominal cavity. The occurrence of fæcal vomiting is not always a pathognomonic sign of ileus, as this vomiting sometimes occurs in other conditions, and when there exists no indication for surgical interference.

The Fate of Ovaries in Connection with Retroversion and Retroflexion of the Uterus.—Dr. Albert Goldspohn, of Chicago, read a paper with the following conclusions: (1) In all cases of retroversion and retroflexion of the uterus a knowledge of the ovaries as to their location, mobility, and general physical condition should comprise an essential part in the diagnosis, as determining largely the nature and urgency of the treatment. (2) The welfare of ovaries, in general, demands such a degree of anterior inclination of the longitudinal axis of the uterus as will enable intra-abdominal pressure to bear upon the posterior surface of the organ, and thereby to act in unison with its other supports to retain it and its adnexa in normal position and function. (3) Inasmuch as in the female pelvis as well as elsewhere in the human body the natural and considerable abilities of healthy tissues to defend themselves against microbic invasion (infection) are lowered or annulled in direct proportion to any degree of mechanical embarrassment of the venous circulation in the tissues or organs, it behooves gynæcologists especially to be alert in recognizing and correcting all material anomalies in place or posture of the female generative organs or in securing to them their normal freedom.

The Administration of Phosphate of Strychnine during Gestation.—Dr. Walter B. Drosett, of St. Louis, Mo., read a paper with this title. The following good results have been gained by him in the use of this drug during the gestation of weak and debilitated patients: A good appetite and good assimilation are obtained in the general weakness and debility of the anæmic. Constipation is relieved, the patient is built up and placed in a good condition to pass through the ordeal of labor. The uterus contracts promptly after the third stage of labor, and the use of ergot is entirely dispensed with. If he finds it necessary to use the forceps the patient is given a hypodermic injection of one-thirtieth grain of sulphate or phosphate of strychnine as soon as the anæsthetic is commenced, but no ergot is ever used. After the continuous use of the phosphate of strychnine, the uterus contracts promptly after the second stage of labor, and in many

cases the application of Credé's method of expression of the placenta is not needed to bring it away, and no post-partum hemorrhages have occurred. The frequently observed chilliness or rigors which in the majority of cases follow labor have been noticed in but few cases. For some time in his abdominal surgery he has used strychnine for the purpose of preventing shock and to control the pulse in operations, and in this way was led to its use in obstetrics. As phosphorus and strychnine are remedies used in the treatment of rachitis with good results, would it not be the remedy during the gestation of the rachitic fœtus?

———

Fourth Day—Friday, August 20th.

Appendicitis.—Dr. George S. Peck, of Youngstown, Ohio, read a paper in which he reported fifty-two cases illustrating his personal experience with the medical and surgical treatment of appendicitis. He said there were four cardinal symptoms which will almost invariably insure a correct diagnosis, if they occur in the order given. First, sudden severe pain in the abdomen, generally of a colicky nature, located in any part or extending over the entire abdomen. Second, always nausea and frequently vomiting. Third, increased temperature. Fourth, localized tenderness in the right iliac region. Some patients will have diarrhœa, while others may be constipated. He had never failed to make a correct diagnosis when the four cardinal symptoms were present. Surgeons differ in their methods of operating. Some advise in the acute suppurative form simple incision and evacuation of pus. If the appendix cannot be easily found, it should be left, drained, and packed, and then in the interval between attacks the appendix should be removed, always provided one can get the consent of the patient, which the speaker has found to be difficult. A few surgeons advise the liberating of all adhesions and the removal of the appendix in all cases of acute suppurative appendicitis, and have reported good results. He believes it is the duty of every surgeon to make a complete operation in the vast majority of cases, and thinks that the time is not far distant when all surgeons will advise the breaking up of all adhesions, the removal of every diseased appendix, and the closing of the incision as is now done in the operation for pyosalpinx, as advised by Morris, Price, and McMurtry. In his last three cases he had followed this method and the results had been far beyond his expectations. Two of the cases were discharged in three, and one in four weeks.

Dr. Lewis S. McMurtry, of Louisville, Ky., followed with a paper entitled "The Operation Itself in Appendicitis," in which he considered the subject under the following headings: 1, the incision; 2, dealing with adhesions and with abscesses; 3, removal of the appendix; 4, drainage and isolation of the peritoneum by gauze. Concerning the incision three important considerations must be observed. The first is to obtain easy access to the caput coli with sufficient working-space; second, to secure all natural advantages to facilitate drainage; third, to do the least damage possible to the parietal structures incised in order that firm union may be secured and hernia thereby prevented. The early operations for appendicitis are mostly in extreme cases, wherein suppuration has obtained, and consist in cutting down into an abscess and evacuating and draining the same. For this purpose the vertical incision was adopted and is yet practised by many surgeons. This incision does not, however, in his opinion give so easy access to the appendix and to the outer and posterior areas adjacent thereto, which are so frequently involved, as does the oblique incision. A method of dividing the abdominal wall by a combination of incision and blunt dissection has been described by McBurney and commended by many writers on surgery of the appendix. This incision was described at length. In dealing with adhesions and abscesses the same general rules of surgical treatment should be observed in appendicitis as in similar conditions affecting other organs inclosed within the peritoneum. Whenever practicable, adhesions should be separated, abscesses emptied, disintegrated structures composing foci of infection removed, and cleansing and drainage secured by measures of assured efficiency.

In his early operations he ligated the appendix with the meso-appendix, using fine silk sterilized, cut away the appendix, and applied pure carbolic acid to the stump. Later he adopted the modern method of transfixing the meso-appendix at its base, cutting it away, stripping back a cuff of peritoneum from the appendix down to its junction with the cæcum, ligating the appendix with fine silk and cutting it away, sterilizing the stump, invaginating the stump into the cæcum and covering with peritoneum by careful stitching after the Lembert method. Nothing in the progress of healing or in ultimate results indicated any advantage of the latter method over the former simple ligature, excision, and cauterization.

Senile Irritable Uterus.—Dr. Thomas J. Maxwell, of Keokuk, Iowa, contributed a paper on this subject. In three cases he was unable to relieve this condition by tentative treatment, and finally resorted to hysterectomy with complete success in all of them.

The Election of Officers resulted as follows: *President*, Dr. Charles A. L. Reed, of Cincinnati, O.; *Vice-Presidents*, Dr. Richard Douglas, Nashville, Tenn., and Dr. Walter B. Dorsett, St. Louis, Mo.; *Secretary*, Dr. William Warren Potter, Buffalo, N. Y.; *Treasurer*, Dr. X. O. Werder, Pittsburg, Pa.

Place of meeting, Pittsburg, Pa. Time, September 20, 21, and 22, 1898.

Therapeutic Hints.

Diphtheritic Paralyses.—

℞ [illegible] . . . . . 1–4 gtt.
Strych. sulphat. . . . . gr. ¹/₃₀.
Aquæ . . . . . f℥ss.
M. S. [illegible] every four years of age.

—L. Simon.

Antiseptic Powder.—

℞ [illegible] . . . . . 1 gr.
Ac. boric 28.34
[illegible] 0.60
[illegible] 56.66
M. S. For external use.

—Pick.

Gout.—

℞ Tr. stramonii . . . . . ♏ i.
[illegible] . . . . . ♏ xxx.
[illegible] . . . . . ♏ i.
M. S. Teaspoonful three times a day in milk.

—Gayle.

Non-Diphtheritic Throat Affections in Children.—

℞ [illegible] . . . . . ♏ xx.
Sweet almond oil . . . . . ♏ i.
[illegible] . . . . . ♏ xx.
Distilled water . . . . . ♏ iiss.

Peppermint, orange-flower water, vanilla, or cherry-laurel water may be added to make aromatic. Salol should be suspended if the urine appears of a dark color.—De la Carrière.

Treatment of Laryngeal Tuberculosis.—Dr. Jankenevitch says the principal element of treatment consists in the application of chloride of zinc and carbo-

lated glycerin, in strength of 1 to 10 or 1 to 5, according to the nature of the case. The following antiseptic spray is advised:

℞ Acid. boric.	5 gm.
Acid. phenic.	60 cgm.
Glycerin.	50 gm.
Aquæ laurocerasi.	50 gm.
Aquæ.	450 gm.

This is especially valuable in the initial catarrhal stage. *Journal de Médecine*, February 10, 1897.

Treatment of Epilepsy.—As an adjuvant:

℞ Zinc. oxid.	0.10 cgm.
Pulv. valerian.	0.10 "
Pulv. bellad.	0.01 "
Sapon. medic.	q.s.

S. To make one pill. Take four daily.

Treatment of Fetid Bronchitis.—

℞ Hyposulphate of sodium	15 gm.
Distilled water	60 "
Simple syrup	25 "

—Polli.

Treatment of Diabetes.—In an article upon treatment by means of a diet from which all carbohydrates have been excluded, Dr. Edward L. Munson draws the following conclusions in *The Journal of the American Medical Association*, May 15, 1897: 1. Sugar is always present in the blood. 2. The absence of carbohydrates from the diet does not cause a disappearance of the blood sugar. Hence sugar must have some other source than the carbohydrates ingested. 3. This other source of sugar is the ingested and systemic albumin elaborated through a process of decomposition. 4. An increased albumin decomposition due to the rigid enforcement of a purely nitrogenous diet means an increased metabolism and consequent loss of body weight. Hence the cutting off of carbohydrates from the diet directly produces an increased metabolism. 5. *Vice versa*, the administration of carbohydrates retards metabolism. 6. The diabetic has an especial predisposition toward metabolism. 7. The diabetic has by no means lost the power of burning sugar; therefore sugar must, even more than in health, be allowed, in order to prevent loss of weight and muscular weakness, which may result in one of the natural endings of diabetes, death by asthenia. 8. The abnormal albumin metabolism, which is especially produced by a rigid proteid diet, results in the production of toxic bodies. 9. The depressed nervous condition of the diabetic is especially favorable for the action of these bodies. 10. The production of toxic bodies is prevented or retarded by the administration of carbohydrates. Hence carbohydrates should be administered to the diabetic to prevent the formation of certain toxic bodies and the severe and often fatal nervous and cerebral symptoms which they induce.

Faulty Hydrotherapy. — Dr. Baruch concluded, in a paper read before the German Medical Society of New York: 1. That the therapeutic application of water demands at least as much care as the use of medicinal agents. 2. That, owing to the flexibility of water as a remedial agent, in its use greater demands are made upon the practitioner than in the use of medicines. 3. That the best results may be obtained only by following an exact technique in each case. 4. That the reason different results are obtained by different physicians from the application of water may be found in the technical errors committed on account of an erroneous conception of the *rationale* of hydrotherapy.

Chorea. Krafft-Ebing (*Allg. Wien. med. Ztg.*, 1897, B. iii., S. 5), in speaking of the treatment of this disease, lays stress upon the attainment of "peace of mind and body." A milk diet may be given and the patient should be out of doors as much as possible. Warm baths are recommended. In chorea gravis sleep may be produced by means of the wet pack; if hypnotic drugs are called for, amyl hydrate, four grams per diem, trional, urethan, and in the worst cases chloral hydrate, are employed. In treating the general condition nothing approaches arsenic for allaying the general irritability of the nervous system; nux vomica may also be of service. Chorea in adults over thirty years comes on slowly, is difficult to subdue, and its victims often develop *tædium vitæ* and suicidal impulses. In one case of this kind it was found that hyoscine acted with benefit for a time, but later on the disease progressed.

Cancer of Stomach.—To control the vomiting:

℞ Picrotoxin.	0.05 cgm.
Morph. hydroch.	0.05 cgm.
Atropin. sulph. neut.	0.01 cgm.
Aq. laurocerasi.	20 gm.

S. Five to eight drops before meals.

—Albert Robin.

Diabetes Mellitus.—

℞ Lithii carbonat.	gr. xxx.
Sodii arseniat.	gr. i.
Ext. gentianæ.	gr. xv.

M. ft. massa et in pil. No. 20 div. S. One pill morning and evening.

—Vigier, *Annual Univ. Med. Sci.*

Follicular Tonsillitis.—

℞ Olei creosoti.	gtt. viij.
Tinct. myrrhæ,	
Glycerini.	āā ℥ ij.
Aq.	ad ℥ viij.

S. Use as a gargle every two hours.

—Levy, *Medical and Surgical Reporter*.

Itching of Urticaria.—

℞ Distilled water.	450 parts.
Cherry-laurel water.	50 "
Chloral hydrate.	5 "
Cocaine hydrochlorate.	3 "

—*Provence Médicale.*

Scarlatina.—

℞ Tinct. ferri chloridi.	℥ ij.
Potassii chloratis.	ʒ i.–ij.
Syr. simplicis.	℥ iv.

M. S. A teaspoonful every hour or two to a child of four or five years.

—J. Lewis Smith.

Superficial Cancer without Ganglionic Involvement.—

℞ Acidi arsenosi.	1 gm.
Alcohol, ethyl.,	
Aq. dest.	āā 75 "

Paint the surface daily. As the eschar grows thicker increase the strength to 1 in 40.

—Czerny and Trunecek, *La Sem. Méd.*, May 1st.

Malignant Pustule.

℞ Hydrarg. bicyanid.	1
Aq. dest.	100
Cocainæ salicylat.	q.s.

M. S. Inject from half to one syringeful subcutaneously and cover the area with sublimate compresses.

—Kedroff.

Ergot in Post-Partum Hemorrhage.—Dr. Lombe Atthill (*British Medical Journal*, March 6th) gives the following results of his experience in regard to the use of ergot: 1. When administered previous to the termination of pregnancy in the case of women in whom a marked tendency to post-partum hemorrhage is known to exist, it tends in a marked manner to prevent the occurrence of hemorrhage. 2. When so

administered in ordinary doses, it does not induce any injurious effect on either mother or child, and its exhibition seems to delay the commencement of labor in such cases. 3. It tends to make the involution of the uterus more perfect, and lessens the chance of occurrence of subsequent uterine troubles, many of which depend for their cause upon imperfect involution of that organ. 4. It will not bring on premature labor or induce abortion, unless uterine action has previously been set going. 5. In cases of threatened abortion its administration frequently seems to act as a uterine tonic, and in some cases tends to avert the danger of a miscarriage, provided the ovum be not blighted. 6. If the ovum be blighted, and especially if it be detached, ergot usually hastens its expulsion.

—

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

UNEXPECTED ELECTION—MEMORIAL ON MEDICAL-AID ASSOCIATIONS—SANITARY CONGRESS—HOSPITAL FUNDS—DEATH OF DR. TURNBULL.

London, September 17, 1897.

We are soon to be troubled with another election of a representative of the registered practitioners in the General Medical Council, for Dr. R. R. Rentoul has already resigned his seat, having apparently had enough of it in one session. I very much regret his resignation, his supporters generally are grievously disappointed, and even those who are opposed to his views seem sorry that he should throw up the opportunity of keeping them before the profession in the council itself where other opinions prevail. Howbeit, he perhaps has sufficient reason to justify himself in his own mind for abandoning this important part of his work. It is to be hoped he will not give up the special department of reform which secured his election.

Who is to succeed him is the question of the day. Two former candidates are already in the field—Mr. Jackson, the nominee of the Incorporated Practitioners' Society; and Dr. Diver, who is an independent candidate. Two others, Drs. Woodcock and Drage, decline to contest the seat on this occasion, but are willing to come forward in the future.

Mr. Victor Horsley, F.R.S., is also willing to serve, and the excellent work he has done for medical defence should insure him a wide support, while his scientific position would give him a respectful hearing in the council.

It is suggested in some quarters that Sir W. Foster should be induced to resume his place in the council, but I see no reason for inviting the return of one who might, had he desired, have continued to sit; and he is merely the mouthpiece of the older clique of the British Medical Association. In reference to this, it is curious to notice the change in tone toward the association lately adopted by *The Lancet*, which now seems to think that this numerous body should nominate a candidate and carry him by force of numbers and a ready-made organization. Now, on the 1st inst., *The Times*, referring to the meeting at Montreal, took occasion to deliver a scathing criticism on the uselessness of the association, which, while it has been bitterly resented by the wirepullers, has given no little satisfaction to many thinking men. Of course the *Journal* could not ignore the attack, and on the 11th inst. entered on its defence, and as usual claimed the credit of having initiated and carried all the reforms, legislative or other, which have been accomplished in matters medical for this long time. More curiously, too, *The Lancet* of the same day took up its parable on behalf of the association it has so often had occasion to criticise. Perhaps *The Times* article was a little severe and not absolutely free from inaccuracy, but its appearance has given profound satisfaction to a large number of the profession, both within and without the association.

The medical men of Yarmouth have agreed upon a memorial to the various licensing bodies anent the aid associations, in which they ask the corporations whether they consider holding these appointments compatible with the conditions on which the diplomas or degrees were granted; if holding them does not contravene the regulations; whether they consider that in the interests of the public and the profession bylaws forbidding such practice should be adopted; and whether they do not consider holding such appointments should be declared by the Medical Council "infamous conduct in a professional respect," and, if so, whether they will instruct their representatives on the council to support such a declaration.

The memorial gives a summary statement of the abuses which have led to this action, and may perhaps be followed up by other local medical societies. Unless a general movement of the kind takes place, it is probable that the universities and corporations will continue their course of inaction.

The Sixteenth Sanitary Congress was opened at Leeds on Tuesday, and is still sitting. The addresses on "River Pollution" and "Sanitary Inspection" excited a good deal of interest. Major Flower traced briefly the history of the management of the great northeastern watershed, covering six hundred miles, which furnishes a considerable proportion of the London water supply. He urged the necessity of further legislation as to the fouling of streams, and advocated the abolition of all exceptions or special clauses, and would make it a penal offence to pollute any river or stream.

The Prince of Wales' hospital fund now amounts to nearly £184,000.

Dr. J. Muter Turnbull, F.R.C.P., formerly of Liverpool, died on the 7th inst., aged eighty, having been for years a martyr to chronic rheumatic arthritis. He was physician to the Royal Infirmary from 1849 to 1876, and enjoyed a leading position in the north of England. In 1881 he went to Cannes for failing health, and there the rheumatic affection declared itself. After the manner of this dire disease, successive attacks followed and eventually completely crippled him. For several years he had lived at Tunbridge Wells, which seemed to suit him as well as anywhere, and where I had the opportunity of witnessing his patience in his suffering and infirmities, which were as far as possible alleviated by the ministrations of his devoted wife.

WHO INTRODUCED THE TERM "APPENDICITIS"?

To the Editor of the Medical Record.

Sir: In the Medical Record for January 23, 1897, page 142, Dr. Gerster, of New York devotes nearly an entire column to an attempt to "abolish appendicitis;" and although he says he neither "knows nor cares" who is responsible for this "philological monstrosity," and "that the reckless ease with which the word was coined cannot be excused by the difficulty or impossibility of finding a better, more rational, and yet intelligible expression," and goes on to offer "scolecitis" as a substitute, the pages of the Medical Record fail to show that his suggestion has as yet met with

any favor. It is more than probable that "appendicitis" has come to stay. In Mr. Christopher Heath's annual address before the surgical section of the British Medical Association recently at Montreal, he said: "I do not know to whom we are indebted for the hybrid term appendicitis, but it did not appear in the index to the *British Medical Journal* before 1891."

The fact that the origin of this term was unknown to these two eminent surgeons led me to think that it was not very widely known that Dr. Reginald H. Fitz, of Harvard, is responsible for the term appendicitis. In the article on "Appendicitis," in the "Practice of Medicine" by H. C. Wood and R. H. Fitz, p. 876, is this statement:

"The importance of recognizing the vermiform appendix as the usual source of the inflammations in the right iliac fossa, whether designated iliac abscess, iliac phlegmon, typhlitis, perityphlitis, paratyphlitis, or typhlo-enteritis, led Fitz to offer the term appendicitis to indicate the primary disease whose results were so variously named. Despite the barbarism of the term, its practical importance has made it welcome." A. B. ROSENBERRY, M.D.

[illegible], Wis., September 17, 1897.

TAPEWORM IN MAN.

To the Editor of the Medical Record.

SIR: In reference to the statement of Dr. E. C. Chamberlin in your issue of August 28th, that tapeworm is confined to females, I beg to state that one of the most perfect specimens I have ever seen came from one of the students of the Atlanta, Ga., Medical College last winter. So perfect was it that I secured the worm for the college museum. This is one case, at least, in a male. C. M. BLACKFORD, JR., M.D.

Atlanta, Ga.

"HOSPITAL ENTERPRISE."

To the Editor of the Medical Record.

SIR: The undersigned physicians and surgeons, constituting the medical and surgical staff of the Omaha Hospital and Deaconess Home, wish to state, in reference to an item which appeared in the MEDICAL RECORD of August 28, 1897, under the title of "Hospital Enterprise," that they are in no way responsible, directly or indirectly, for the appearance of the circular referred to in said item. Said circular was prepared by the members of the board of trustees, and by them ordered to be mailed to every Methodist minister within a certain radius of Omaha, without consultation with or the knowledge of any member of the staff. The clerk, in accordance with her instructions, began mailing the circular, when accidentally a member of the attending staff discovered the nature of the mail matter, and after his remonstrance, and after only a small number had been mailed, its further distribution was promptly discontinued and the remainder destroyed.

We therefore desire in the most public manner possible to express our most emphatic disapproval of said circular.

W. O. BRIDGES, M.D.,
HAROLD GIFFORD, M.D.,
A. F. JONAS, M.D.,
W. S. GIBBS, M.D.,
J. M. AIKIN, M.D.

The Vagina when washed out with sublimate or carbolic solution in strength sufficient to free it from germs will become dry and chapped.—DÖDERLEIN.

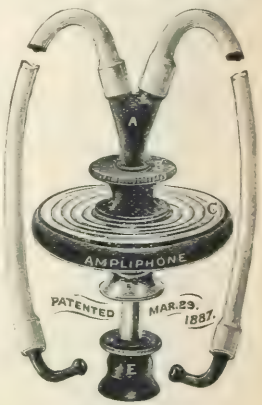
New Instruments.

THE AMPLIPHONE—A NEW INSTRUMENT DESIGNED TO REPLACE THE ORDINARY STETHOSCOPE.

BY J. H. CLARK, M.D.,

[illegible], N. Y.

SOME few weeks ago my attention was called to a new instrument which had but just made its appearance before the medical public, and being interested in any appliance, device, or means by which physical diagnosis may be made more simple and at the same time more correct (and as well a bit curious) I secured one of the instruments, which I have used for perhaps six weeks with results which have been highly satisfactory in nearly if not quite every case: in fact it has developed a condition of affairs in several instances which has been of the greatest importance not only to the examined but to the examiner as well; and thinking others might be interested, I venture to report the result of my experiments with this latest addition to the list of stethoscopic instruments.



The instrument consists of two aluminium diaphragms of two and a half inches in diameter. The metal, which is extremely thin, is corrugated in circular lines. Between the diaphragms is placed a brass ring, about a quarter of an inch wide, into grooves in which the edges of the diaphragms are spun or pressed. An air chamber is thus left between the inner convolutions of the diaphragms. Projecting from the upper diaphragm is a metal stud, covered with hard rubber, for convenience in handling. Through this stud passes a tube one end of which is attached to the tubing which carries the sound to the ear, as in the phonograph. This tube runs down to the air chamber between the two diaphragms. To the centre of the opposite diaphragm is attached a bell-shaped terminal, through which a tube runs to the outer surface of the diaphragm. This cup-shaped terminal is applied to the locality from which the sound is supposed to emanate. An extension piece is provided to facilitate the handling of the terminal in certain cases by the practitioner. The whole appliance weighs about two ounces and can be carried in the pocket.

The following cases coming under my observation and in which the ampliphone was used may be of some interest, viz.: Three cases of pregnancy, in two of which the diagnosis was doubtful owing to the absence of certain symptoms and the uncertainty of others. The doubtful cases were examined carefully with several varieties of stethoscopes without the fœtal heart or uterine souffle being heard until the ampliphone was tried, when both were recognized; not only was the diagnosis confirmed but a fairly correct idea of the position was secured.

The third case was one in which circumstances did not permit the removal of the clothing, but the sounds were transmitted with remarkable clearness through

the ordinary dress worn by the patient and heard without the slightest difficulty.

Two cases, one of organic heart lesion complicated with emphysema, and the other of uræmic coma, in both of which the respiratory murmur was so greatly exaggerated that the heart sounds were rendered indistinct, furnished an opportunity to test the pulse with the ear as well as the finger, and in both cases the sound was transmitted with sufficient strength and clearness to enable it to be counted with ease, while its volume and character could be determined without difficulty; there were two other physicians present on this occasion, both of whom listened and expressed their satisfaction at the result.

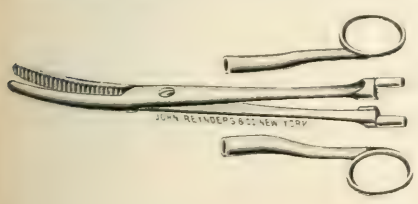
In a case of lobar pneumonia the tubular breathing seems magnified or intensified very considerably by this instrument as compared with the ordinary stethoscope, while the whistling râles of emphysema, the coarse rattle of bronchitis, and the friction of pleurisy are carried to the ear so pronouncedly louder that one with difficulty realizes what he hears. I believe this little instrument possesses several decided advantages over other appliances for a like purpose and that its field of usefulness is of the widest range; in the hands of men of skill and intelligence it will be of the greatest assistance in diagnosing and treating disease.

HYSTERECTOMY FORCEPS.

By W. R. BROOK, M.D.

For two years and more, I have been using a kind of forceps in my vaginal work which seem to have advantages over and to be devoid of objectionable features which attach to other forceps. They are very easily applied; and the forceps placed to secure the uterine arteries are scarcely felt to be in the way while the manipulation of the higher structures is being performed. Furthermore, the forceps without their handles, when moved by the operator's hands, exercise less leverage upon the stumps than do longer instruments. The catch is perfectly secure, and is made in such a way that the points of the bite meet when the first catch is closed.

After the operation is completed and the forceps are surrounded by a gauze dressing, the mass of instruments does not interfere with the use of a catheter and does not prevent the patient turning about when restless: there are no long handles to be jarred by her thighs. In removing the forceps the keys are applied and the instruments released one by one. I have stipulated with the makers that these instruments shall be made of tempered steel from one end to the other. If there be flaws in a pair they will break in their application, and not bend and twist under the strain and admit of



bleeding. They render the after-conduct of hysterectomy cases simpler, and lessen the discomfort incident to the operation. They have been so thoroughly tried that I feel I can recommend their use to the profession.

Earth-to-Earth Burial.—At the recent nineteenth annual meeting of the Church of England Burial-Reform Association, Dr. Toore, on contributing a paper on "Earth-to-Earth Burial," laid stress upon the fact that the earth was a source of life in this world and the necessary recipient of all dead organic matter. With due regard to scientific principles it was quite possible to carry out the rite of burial, not only without harm, but with a certain amount of benefit to the living. If bodies were buried in the upper layers of the soil, and in contact with it, a complete disappearance of the organic matter would be effected in about twelve months. A cemetery scientifically used and planted formed an open space which was invaluable to crowded centres of population, and by affording nourishment to trees and other green-leaved plants had the power of freshening the air. The simplification of funerals and scientific burial, so that the ground might be used a second time after a certain interval, were both important steps in the advance of sanitation.

The Origin of the Word "Deadhead."—Fifty years ago the principal avenue of Detroit, Mich., passed close to the entrance of the plank road leading to Elmwood Cemetery. As this cemetery had been laid out some time previous to the construction of the road, it was arranged that all funeral processions should be allowed to pass along the latter toll free. One day as Dr. Pierce, a well-known physician, stopped to pay his toll, he observed to the gate keeper: "Considering the benevolent character of our profession, I think you ought to let us pass free of charge." "No, no, doctor," replied the gate keeper; "we can't afford that. You send too many deadheads through as it is." The story travelled around the country, and the word "deadhead" was eventually applied to those who obtained free admission to the theatre.

The Physical Effects of Music.—Experiments on the influence of music upon respiration, recorded by MM. A. Binet and I. Courtier in the *Année Psychologique* for 1897, indicate that musical sounds, chords, and music in general, as a sensorial excitation independent of all suggested feelings, provoke acceleration of respiration, increasing as the movement is more lively, without disturbing the regularity or augmenting its amplitude. The major mode is more exciting than the minor. The heart is similarly affected. The distinction between sad or solemn and lively music appears to be for the most part wholly theoretical, and hardly squares with the complexity of the musical emotions produced by the melodies with the infinite shadings suggested by the ideas of the libretto. The authors, however, infer from their researches that the acceleration of the

heart and of the respiration was not so marked during the hearing of sad pieces as in those in which joy and high excitation of musical emotions prevail.—*Ayer's Sarsaparilla Monthly.*

The Antivivisection Pledge.—"I pledge to never knowingly employ a physician practising or upholding vivisection unless in case of immediate danger or death." The antivivisectionist is evidently as great a foe to grammar as she is to any other science.

"Cock-Matrons."—Subsequent editions of dictionaries of the English language will have to find space for a new compound word, namely, "cock-matrons." Possibly some of our readers will be curious to know whence this term originated. We will enlighten them. The term heads an editorial article, which appeared last week in a contemporary published in the sole interests of nurses, called the *Nursing Record*. This journal, as is generally known, is conducted by a lady, who may be assumed to know something about matrons, inasmuch as she was once matron herself to a large general hospital in London. The article in question altogether disapproves of men having anything to do with the appointment or selection of the nurses at hospitals. "It has," says the writer, "been proved over and over again that man is rarely a competent judge of the capacities of women for work. Smartness, good looks, a taking manner, or a pretty bonnet have often turned the scale in favor of a candidate for a post when the appointment is made by men." Upon these grounds, then, "cock-matrons" must be condemned as impracticable hermaphrodite officials, whose judgment would always be certain to be biassed and at fault. But perhaps the best way of dealing with this subject is to discuss the objectionable species of "cock-matrons" from a morphological point of view. It is then that the matter becomes very interesting, as those having a taste for morphology will soon discover. Upon the whole, however, we prefer to leave to our readers the pastime of working out for themselves the various problems which it suggests.—*Medical Press*, August 4, 1897.

Health Reports.—The following statistics concerning cholera and yellow fever have been received in the office of the United States Marine Hospital service during the week ended September 25, 1897:

THE CHANGE OF LIFE AND THE DIAGNOSIS OF CARCINOMA UTERI.[1]

BY EDWARD J. ILL, M.D.,

NEWARK, N. J.

UPON inquiry among my medical friends what subject for an address might be of sufficient interest and importance to the county society, I found the most diversified opinion. The gentlemen all agreed in this, however, that the early diagnosis of carcinoma of the uterus was frequently very difficult and often gave them much annoyance. Having occasion to look over my notes of cases of cancer of the uterus, I was astonished at the number of patients who came with the opinion that they suffered from symptoms of the menopause. Thus this subject seemed to me the proper one for discussion. Cases are often referred to me months after the first symptoms, these symptoms being spoken of as belonging to the change of life. Of course, operative interference cannot be thought of, the disease having gone beyond the limit of the uterus, much to the disgust of the family of the patient, and often to the professional and business detriment of the attendant, not to speak of the misery of the poor sufferer, when there might have been a chance for cure. Somewhere I read this very true statement: "The best therapy which a woman with carcinoma of the uterus can receive at the hands of the practitioner consists in an early diagnosis."

It is the duty of those who have family practice to give women some idea of the innocent symptoms accompanying the menopause; to teach them that the menopause means a cessation of the flow, not an increase, and to insist on an immediate examination if anything occurs which is not plainly and solely attributable to this condition. It will be better to err on the wrong side and make too many examinations. Nowadays, women rarely object when the matter is properly placed before them. I would, however, strongly disapprove of frightening the patient into an examination by threatening her with the word cancer. With that word one can get a woman to consent to almost anything.

I will not annoy you with a lengthy enumeration of the symptoms accompanying the menopause. A few, however, will be of value as compared with the symptoms of malignant disease. The chief factor that will interest us in this regard is the quantity, quality, and regularity of the flow of blood. By the change of life is understood that condition in which the woman normally and finally ceases to have a regular monthly bloody flow. The ideal change would take place if she gradually ceased flowing by longer and longer intervals. This, however, is rare, and she suffers more or less from irregular flow, at times anticipating and more frequently postponing. Usually the flow becomes more and more scanty, rarely excessive. When the latter, it is commonly due to endometritic changes, and frequently is found in women who were sufferers from some pelvic difficulty for years. Now and then there is no apparent cause, and I was once obliged to extirpate the uterus to save the patient's life. It was then discovered that a small polypus was the cause of the hemorrhage. Nervous symptoms are the rule, but rarely consist of more than vasomotor disturbances of the skin, hot flashes, profuse and sudden perspiration. Vertigo and palpitation of the heart are not infrequently met with. Now and then we see neuralgia, insomnia, and mental depression.

With the laity change of life means almost any abnormal symptoms, physical or otherwise, which a woman may have from the time she is thirty-five until she has reached sixty, so vague is the woman's notion of this dreaded time of life. It will be irrelevant to our subject to draw your attention to the peculiar atrophic changes going on in the genital organs with the normal cessation of menstruation, except, perhaps, that malignant or ovarian growths are not affected by the menopause; but fibromyomata commonly undergo retrograde changes by which they become smaller, and in several cases I have seen complete absorption take place. Now and then malignant changes have been said to take place in fibromyomata and ovarian tumors at this time of life. There is, however, nothing especially to characterize this change. After what has been said, the diagnosis of climacteric changes and disturbances should not be difficult. The prognosis is good, provided a careful examination has revealed no pathological changes in the uterus which would lead to a suspicion of malignant degeneration.

This brings us to the discussion of the diagnosis of carcinoma of the uterus. There are no symptoms characteristic of carcinoma of the uterus. Pain, hemorrhage, or other discharges are also factors in other ailments than carcinoma. It is here that we have committed grave sins of omission, because we have not insisted upon an immediate and thorough pelvic examination in a woman who presented symptoms referable to the genital tract in the time of life under discussion. We must start out with the knowledge that women at forty-five or fifty years of age do not flow excessively without local or general cause, any more than do women at twenty or thirty. In more than fifteen thousand gynæcological cases I have seen hemorrhage but three times at this period of life which could not be explained by some special ailment. There are predisposing causes in the chronic inflammatory changes about the uterus. Unfortunately, early symptoms of carcinoma of the uterus are not always so prominent as to induce the patient to seek timely medical advice. Nor should the doctor look for symptoms which do not come on until the later stages and often the last stages of the disease are reached. All this proves to be a great calamity for our women.

When a woman has a return of a protracted bloody flow anywhere after six to ten months from what was thought to be her last menstruation, our suspicion must be directed to a probable malignancy as a cause. In fact, we shall rarely find anything else if such a return takes place two years or more since the last period. Now and then a mucous polypus is found to be the cause. Besides this bloody

[1] President's address, read before the annual meeting of the Essex County Medical Society, April 6, 1897.

flow, a constant serous or sero-sanguinolent discharge is almost invariably present. Unfortunately, however, this is not always an early symptom. These few symptoms alone make an examination imperative. Greater difficulty, however, is experienced in detecting the earlier symptoms in women who are still in the active period of sexual life. Here we rarely find more than an increase in the quantity of menstrual flow, possibly a little prolonged. This is most frequently due to an accompanying hyperplastic endometritis. A little later the flow will be more frequent and soon it becomes constant.

Carcinoma of the body is more apt to present these symptoms than carcinoma of the cervix. With carcinoma of the cervix, often the earliest symptom which brings the patient to the doctor will be a show of blood after marital intercourse, severe exertion, or a constipated movement. When we once get irregular hemorrhages, and by hemorrhage I mean excessive flows of blood, we have already reached the stage of erosion or breaking down and have generally passed the time when operative interference offers a fair chance. Pain and cachexia are always late symptoms. I am sorry the word "cachexia" was ever invented—so many rely on the appearance of this symptom before they dare to diagnose cancer. As has been said, pain also is a late symptom and shows itself when the disease has reached beyond the uterus proper. There is an exception to this in many cases of carcinoma of the body of the uterus, when an intermittent, agonizing pain, most frequently late in the afternoon or toward morning, is recognized early. Foul odors are not pathognomonic of malignant disease. They are a late symptom and should not be waited for. They come on comparatively early in the unclean and those who have been treated locally, from the fact that air with its decomposing germs has entered the passages.

You will see from what has been said that an early diagnosis from subjective symptoms belongs to the difficult problems. With these subjective symptoms we must consider the objective as presented by thorough and exhaustive physical examination. It is not in the province of this paper to go into the fundamentals of a pelvic examination; let it be sufficient to touch on those points which at the bedside will make the diagnosis highly probable. For convenience' sake malignant disease of the cervix and corpus will be spoken of separately.

Of the several forms of cervical carcinoma, the cauliflower growth will give us the least difficulty in diagnosis. The uneven, friable, and easily bleeding surface projects so far from the cervix itself that the cervix proper can hardly be reached. The mass fills up a considerable portion of the vagina. This condition is quite pathognomonic, and is easily distinguished from the hard solid polypus or the hypertrophic cervix. The superficial surface of the excrescence is eroded and covered with a grayish dirty mucus.

The ulcerating epithelioma of the cervix is easily known by its distinct hard edges, the hardness extending somewhat beyond the ulcerating portion. The bottom of the ulcer is remarkably hard, but so friable that a curette will easily remove a large piece. A tenaculum will find no hold in it. In the speculum it appears as covered by a dirty grayish matter. The ordinary erosion, on the contrary, appears of a red color, has no infiltration of its edges, and is smooth and velvety to the touch. The curette will make little impression on it, except to remove a very superficial layer.

I will not detain you with the differentiation of the rare tuberculous ulcer.

The syphilitic ulcer will be recognized by its general symptoms.

When there is any doubt excision of a portion of the ulcer should be made and subjected to a microscopical examination. It is always well to remove some healthy tissue with the diseased structure for this purpose, and is very satisfactory. Scrapings, on the contrary, are most unsatisfactory.

When carcinoma of the cervical canal exists it will show only when the cervix is dilated and the curette produces the friable masses. By palpation the cervix is found enlarged, and hard, deeply situated nodules are felt. Cervical carcinoma will have to be differentiated from fibromyomata, which will not be difficult.

Carcinoma of the body cannot be diagnosed in its earlier stages by palpation. Here again the curette, besides the subjective symptoms, must tell us the true state of affairs. Carcinoma in this location offers the very best chance for permanent cure by operation. I would rather diagnose this condition by the curette than by the microscope even in the hands of the expert. The microscope can rarely be relied upon in the examination of scrapings. It will often mislead and will be of value only when it gives positive results in connection with other symptoms.

Of all cases of carcinoma that came into my hands hardly one in five was presented sufficiently early for operation. When we consider that only twenty-five per cent of those operated upon remain free from recurrence, we can easily understand that but one case in twenty of those coming to the operator remains well, a most discouraging aspect were it not for the fact that even this one would prove fatal were it not for the interference. You will understand, then, why I dare to urge you to employ every means for an early diagnosis and a possible operation; and, if you will permit me to say it, the diagnosis of change of life must be the very last, and after every other explanation of the symptoms, both subjective and objective, fails. The deaths from operation have been lowered to a very small number, and we can conscientiously recommend an early operation, even though it offers so small a chance for permanent cure.

IMPERFECTIONS IN INTRA-ABDOMINAL DIAGNOSIS.

BY BYRON B. DAVIS, A.B., M.D.

[illegible]

THAT progress in recognizing intra-abdominal disease is being made is certain. That perfection has been reached the most rashly optimistic do not claim. For if the subject is looked fairly in the face, all cant laid aside, self-glorification suppressed, and the question put squarely: How many of the last twenty operations have been destitute of surprises in the operative or postoperative findings?—the honest answer will shock our lay friends and, if he is not accustomed to look at the subject from this point of view, appall the operator himself.

An accurate and complete diagnosis beforehand is important, because then only can the operation be planned and executed in the manner which will give the patient the best chance for life, conserve blood, hasten the work, save tissue, and avert shock. In the great majority of cases unfortunately the diagnosis is correct in the rough only, unsuspected conditions being too often found. Supposedly benign obstructions at the pylorus are found to be malignant; disease of the uterine adnexa is found much more serious than was anticipated, rendering the operative difficulties greater and much increasing the dangers: sometimes, happily, ovaries and tubes supposed to be irreparably

[illegible] the Western Association of Surgeons and [illegible] Topeka, Kan., December 24, 1897.

diseased are found merely to be imprisoned by adhesions and no sacrifice of the organs is demanded; and very often after a carefully planned operation the expected relief does not come, the symptoms not having been correctly interpreted.

It seems to be a matter of pride with some, especially in pelvic disease, to make their diagnosis from the physical examination, paying only slight attention to the patient's past history and present subjective symptoms. The woman is overshadowed by her pelvic viscera. Men who do this most are likely to meet with many unpleasant surprises. The palpable lesion is often the least part of the disease.

In approaching a case of suspected abdominal disease, it is necessary to have more in mind than a few cardinal diagnostic points. Advantage must be taken of every resource which can be enlisted having even a remote bearing upon the case. A little point previously overlooked has been known to clear up an obscure case and make it so plain as to occasion wonder at the former difficulty. To be satisfied that a case is one for operation is not enough—the merest tyro can do that; but the wide-awake surgeon is content only when by careful exclusion his diagnosis has been brought down to an absolute certainty. The man who attempts this always, even though such niceties of distinction are often of no practical value, will soon find that his operative surprises are becoming rare.

The very imperfect and often misleading histories obtained from patients are a frequent cause of error. Some wilfully misrepresent by exaggeration or suppression of facts; more mislead because of weak powers of observation or inability to make a clear statement. One patient with slight symptoms will lead her physician to suppose her to be a great sufferer; another with more stoicism will make light of a desperate condition. Most of the chronic cases are migratory and do not remain long under the observation of any one man. A new man is then "tried," and he takes up the case *de novo*, losing the benefit of previous observations. Before he has been able to get the case well in hand, the patient, true to her instincts, has often passed on to the next physician.

If each person's medical history were made a matter of record, the same as a title to a piece of real estate, the patient always presenting an abstract when consulting a new doctor, it would be a great aid. The labor of such a system would be slight when compared with its advantages. No one would then think of consulting a physician without presenting a medical history as formulated by previous attendants, and many costly blunders would be thus avoided.

At a recent meeting of the Brooklyn Gynæcological Society, the case was reported of a woman dying of slow hemorrhage from a ruptured tubal pregnancy, in which three prominent gynæcologists had had no suspicion of the real condition. One of them stated that if he had been in possession of facts acquired by another physician consulted a short time before, the diagnosis would have been cleared up and the woman's life might have been saved. It is evident how such a record as has been suggested would have been of great service.

The diagnosis of extra-uterine pregnancy, although sometimes extremely easy, is often beset with the greatest difficulties. To distinguish it from pyosalpinx or appendicitis frequently requires the most careful weighing of evidence on the part of the surgeon. After painstaking effort to reject all sources of error, even then the scales sometimes tip the wrong way. In a recent case of my own, after a thorough study of all the symptoms and as rigid a physical examination as the condition of the patient would permit, I could not make a positive diagnosis. The final conclusion was that appendicitis was the most probable lesion; a ruptured tubal pregnancy with slow hemorrhage, there being a slowly rising temperature, came next in probability; and it was not possible entirely to exclude pyosalpinx. The other men who saw the case were equally mystified. The operation revealed the presence of slow hemorrhage from a tubal abortion.

Presence of a surgical lesion of the kidney has been the source of much diagnostic uncertainty, it being often difficult or impossible to determine which kidney is diseased or whether both are implicated. Since the cystoscope and ureteral catheter have been perfected, the accurate diagnosis of kidney diseases has been greatly simplified. In like manner chemistry has come to our aid in gastric lesions. Only a beginning has been made in this matter, but promise is made of much development along these lines. When it is possible to make an early and accurate diagnosis of cancer of the stomach, surgery for its relief can be relied upon to be followed by better results than the past has given.

The region of the gall bladder and ducts is also of great interest to the abdominal surgeon. Here, as well as in some other regions, some of the recent surgical work has been more brilliant than the diagnosis has been refined. It is yet no uncommon thing to explore for stones in the gall bladder or ducts, and find disease of the hepatic flexure of the colon or cancer of the pylorus, and sometimes to find nothing at all. An abnormally long transverse colon, as pointed out by McGraw, doubtless figures frequently in these cases. As he states, if the transverse colon is too long it must bend up or down; it cannot bend up, therefore it bends down at the middle, assuming a V-shape. When fæces accumulate at the point of the V, the bowel becomes heavy enough to put the hepaticoduodenal ligament upon the stretch and twist it sufficiently to occlude the common duct, and symptoms analogous to those of gall-stone obstruction result. McGraw suggests that when doubt exists, if the knee-elbow position relieves the pain, the symptoms are due to an abnormally long transverse colon and not to disease within the gall ducts. In all cases of suspected gall stones, one will do well to keep this abnormality in mind.

In addition to the necessity of making a fairly accurate diagnosis of the pathological condition present in intra-abdominal disease, it is still more important to determine whether the symptom complex for which the patient presents himself is dependent upon the lesion found. Will an operation be followed by enough relief to warrant the operative risk, or will the symptoms be made worse or remain unchanged? This, I take it, is one of the most important questions with which the abdominal surgeon has to deal. A retroverted adherent uterus sometimes produces severe symptoms; sometimes this condition exists for years with the individual in robust health. Severe symptoms may exist in a patient with a fixed uterus, and the symptoms be due entirely to the condition of the uterus; sometimes the uterus has nothing to do with the symptoms. A perfect diagnosis depends more upon the proper interpretation of the symptoms than upon the accurate estimation of the size, position, and degree of fixation of the uterus. And so it is with salpingitis, ovaritis, and a host of other palpable lesions.

Movable kidney is very frequent—being present, it is said, in one of every five to seven women. Sometimes it produces symptoms; usually it does not. When unpleasant symptoms are present, they may be due to the movable kidney or to something entirely different. The ability to make a sharp distinction between symptoms due to movable kidney and those due to other causes, and the inability to make such

distinction, mean all the difference between brilliant results on the one hand and the most bitter disappointment on the other. Many an operation has been performed for anchoring a movable kidney or a prolapsed uterus, when the symptoms were due to general abdominal ptosis, and of course the symptoms were not relieved.

But, do the best one can, it often happens that a full and accurate diagnosis is impossible until the operation is in progress, and here there are also many vexatious questions. In a given case of gall-stone disease, will a simple cholecystotomy be best, or a cholecystenterostomy, or is the trouble due to the ball-valve action of a stone in the common duct, which can be removed by an incision into the duct followed by suture and drainage? Must this tube and ovary be sacrificed, or will the patient's best interest be subserved by puncturing the cysts of the ovary, breaking up adhesions, and straightening the tube, and perhaps anchoring in a new position? Should this suppurating kidney be removed, or is it worth while to incise and drain? These and many other questions are constantly coming up during the progress of the majority of abdominal sections, and the operator's mind must be both swift and accurate, else he will be guilty of many surgical crimes.

In conclusion and by way of summary, it is desired to urge:

1. Great care in getting at an exact anatomical diagnosis, calling in every resource which can have the remotest bearing upon the case, whether it be in the patient's history, the tactile examination, the use of chemistry, physics, or instruments of precision.

2. To work out carefully the relationship between the palpable lesion found and the symptom complex. Is it a relationship of cause and effect, or a simple coincidence? Everything depends upon the correct interpretation of the symptoms.

3. When the operation is in progress, swiftly and correctly to weigh the evidence as to whether the results will be better with sacrifice of an entire organ, or will it be possible to preserve it in whole or in part. Is it better to proceed with the operation, or will the patient's best interests be protected by closing the abdomen, leaving the condition unchanged?

WHAT ARE THE MUSCÆ VOLITANTES? AN ENTOPTICAL STUDY.

BY FRANK P. PRATT, M.D.,

[illegible], U.S.A.

THE histology of the vitreous body is a subject upon which the leading authorities differ. This is, no doubt, due to the extreme difficulty experienced in preparing sections for microscopical study. In fact, the possible changes in structure, due to hardening and preservative fluids, have entered largely into the consideration and modified the conclusions of many investigators. Whether the vitreous has an inclosing hyaloid membrane or not, whether the more or less fluid substance proper is sustained in a transparent reticulum of fibres, or distinct membranous walls inclose it; whether three distinct cells are found, or whether they are merely different forms of the same cell or leucocyte; whether it has distinct nutritive vessels or not—are all questions which have ardent advocates on one side or the other.

Probably the latest and most widely accepted views are as follows: The vitreous is a clear, more or less fluid substance, inclosed in a delicate, structureless hyaloid membrane; throughout its substance runs an equally delicate reticulum, or felted work of fibres; its central canal or lymph channel begins at the papilla of the optic nerve, and extends to the posterior pole of the lens. The matured vitreous contains no vessels, but obtains its nutrition from the surrounding structures, principally the ciliary vessels. Retzius says: "Under high amplification, the entire tissue (vitreous substance) is resolved into a feltwork of exceptional intricacy, composed of the finest fibres, which cross one another in various directions and here and there join in narrow nodal points, without, however, constituting network." Retzius has also observed peculiar glistening spherules or granules in many of the fibres. He is in doubt as to their nature. Piersoll believes that not only are these spherules due to the action of the reagents used, but that some at least of the densely felted delicate fibrillæ seen in certain preparations are also due to the same cause.

Retzius rejects as untenable the supposition that "the presence of the spherules is attributable to the action of reagents employed, since the intervening ground substance remains homogeneous." It is the purpose of the writer to offer evidence, gained through an entoptical study of the so-called muscæ volitantes, in support of the statement that a "feltwork of exceptional intricacy" does exist, but that this appearance of the fibre, so aptly described by Retzius, is largely due to post-mortem changes; that the spherules noted by him in the so-called fibres are not due to reagents employed, as claimed by Piersoll, but are clearly histological elements of the vitreous; that the muscæ volitantes, often described as resembling a string of pearls, when seen entoptically under proper conditions resolve themselves into what appear to be vessels with well-defined walls, which contain within their lumen corpuscles or spherules; that the general arrangement of these vessels answers to the description of the "felted fibres" of Virchow, Henle, and Retzius; that if these are vessels at all, which seems probable, they are the lymphatic vessels of the vitreous substance.

Most writers, when describing the macular region of the retina, point out how the vascular arrangement of this region may be seen entoptically. As this image will be the starting-point in our investigations, we will consider it first. From the trial case take the metallic disc with central aperture, apply the disc to the right eye, so that the puncture will be opposite the pupil; look steadily at the blue sky, or a luminous cloud, while moving the disc rapidly from side to side. Presently a distinct picture of the fovea centralis with its surrounding network of capillaries will be seen. If the movements are skilfully made, even the beginning venous radicles in the immediate neighborhood may be clearly made out. The veins are dark, the rest of the picture has a bluish metallic lustre. No capillaries appear over the fovea, but its surface is covered with exceedingly fine, apparently rectangular tracings, resembling closely the delicate tracings on a diatome. These lines appear wavy. This is due, however, to the motion of the disc, as the wave motion changes its direction whenever the motion of the disc is changed. When a circular motion is given to the disc, the fovea region shows a tessellated arrangement, much as it would appear if we were viewing the surface of the cones of this region in a microscopical section.

As stated in a former paper,[1] the cones offer little or no obstruction to the passage of unchanged light vibrations, which pass on through them as through the other histological structure, and, like the latter, cast their shadows upon the pigmentary epithelial layer. It thus appears probable that we view here the image of the cone cells. If these tracings on the surface of

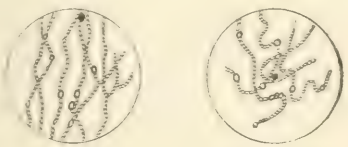
[1] *The Medical Record*, date 1897, "What are the Functions of the Rods and Cones and the Pigment Epithelium Layer of the Human Retina?"

the fovea have been hitherto described, it has escaped the notice of the writer. The capillary network about the fovea greatly resembles a finely spun spider web with its centre removed.

Now stop the motion of the disc and the image will immediately disappear, but when the axis of vision is suddenly changed and again fixed on the cloud fine fibrillary particles containing bright spherules will be seen, gradually settling down in the field. When these are discovered, renew the motion of the disc; the retinal image will again appear, and between it and the observer will be noticed the floating fibrillæ. It thus becomes evident that they are not in the retina; therefore, they are internal to it, and, as they are capable of motion within certain well-defined limits, as will be presently shown, they must lie in the vitreous.

For purposes of more accurate study of these so-called fibrillæ or muscæ, we have recourse to the microscope, not because of any amplification to be derived therefrom, but for its convenience in regulating the amount and quality of light admitted and conveying the rays to a point close to the cornea. Use a one-inch eyepiece and either a one-twelfth-inch objective or the centrally perforated metallic disc; they answer equally well, as the object is to admit divergent rays from a luminous point situated close to the cornea. The larger the opening in the disc, the less distinct the image, so that, if no disc or objective is placed over the farther end of the tube, the field appears comparatively clear. No fibrillæ are discovered. A strong steady light must be used; artificial light is, perhaps, preferable. When thus viewed, it will be seen that the floating particles, which at first resembled a string of pearls or fibrillæ containing spherules, resolve themselves into what appear to be distinct vessels, with well-defined walls, probably composed of indefinite protoplasmic substance. In one of the larger vessels seen by the writer, the walls showed a thickness of about one-half the diameter of the contained corpuscles. This was shown by two indistinct lines running parallel with the axis of the vessel, the intervening substance being of slightly different refractive index than the vitreous fluid (Figs. 6 and 7). Most of the vessels do not show this thickness of walls, a single dark line alone being seen. The calibre of the vessels is of sufficient size to accommodate the diameter of a single cell; therefore the cells fill the vessel in one layer. The cells in each vessel appear to be all of the same size, but some are bright and stand out prominently in the field, sometimes two or more lying in apposition; then a space equal to the diameter of from two to twelve cells may intervene; this space being filled with corpuscles much dimmer in outline but of the same character. After careful and repeated observations, it cannot be definitely stated that the cells have either active or passive motion. This may be due to the fact that these vessels cannot be fixed, but must be studied by indirect vision. The vessels seem to be perfectly flexible, bend freely in all directions, the bend occurring where the corpuscles touch, and in this resemble a string of pearls. The field impresses the observer as being a transparent fluid mass of great depth, throughout which float the vessels, closely corresponding to the description by Retzius of the felted fibrillary arrangement seen in prepared specimens. Especially is this true after violently agitating the intra-ocular contents by rapid movements of the eyeball, and then fixing on a certain spot in the field. The first impression is that the vessels are perfectly free in the vitreous, crossing, interlacing, and branching in all directions and changing their position with every movement of the eye. On closer examination, however, it will be seen that while the motion is apparently free each vessel is limited to a certain and definite portion of the field, so that it can be studied repeatedly after an interval of days or weeks. The sensation of depth is given by a vessel passing in a more or less straight course across the field from above downward to about the middle of the lower half, then turning upon itself, passing and repassing in a tortuous manner across the main vessel, but diverging from it toward the observer or by the principal vessels in the field, passing in front of or behind others that grow dimmer as they recede. Here and there a bright corpuscle will stand out clearly in the field, giving the impression that it is outside of the vessel, but if care is given to the examination the hazy outline of the inclosing vessel will usually be made out. These corpuscles always move with the other vessels and cell elements, and reappear repeatedly in the same part of the field. The writer has discoverd no cells outside the vessel walls. The vessels do not branch in the field, nor, as far as can be made out, join a nodal point.

Fig. 1 represents the general direction of the vessels at rest, with the head in the normal position and the eye fixed on the dot near the upper tangent. After a person has looked rapidly down, then up, then fixed the dot, the vessels after a short interval move rapidly downward, then upward, the latter movement continuing some time after the eye is fixed; then they



stop for an instant before again sinking rapidly downward in the field, the motion gradually becoming slower until the vessels assume the general appearance here represented, remaining practically stationary while the eyeball is absolutely fixed. Any excursion of the visual axis toward a vessel causes it immediately to recede, all the other vessels moving in the same direction. It will be seen that the vessels are arranged in parallel lines, with intervening clear spaces apparently from two to four millimetres wide. Several vessels, however, can be seen occupying the space here represented by one vessel, but they are at different depths in the vitreous, and they dimly cross and recross in front or back of the one shown here. If the head is now turned sideways, so that the outer angle of the right eye corresponds to the upper part of the field, the vessels gradually change their position, first appearing mixed in all directions, then bundles appearing at different levels, finally the vessels gradually straightening out and assuming much the same arrangement as shown in Fig. 1.

Fig. 2 represents a general mix-up after violent agitation of the eyeball and fixation on the central dot.

Figs. 3, 4, and 5 show a part of a vessel that was studied several hours with reference to the position of the bright corpuscles represented. No apparent change could be discovered. Changes in the shape and relation of the vessels, however, are evident.

Figs. 6 and 7 show the appearance of a single loop observed at intervals during three weeks. The corpuscles have nearly the same relative positions, but what appeared in Fig. 6 to be a loop with blind ends now appears continued on in the usual form until it fades away in the distance.

Figs. 8, 9, 10, and 11 show the behavior of a single vessel when the visual axis is moved, first, down; second, up; third, right; fourth, left. The up-and-

down movements are accomplished by changes and contortions of the loop, all taking place in a perpendicular direction. The lengthening of the vessel is at the expense of the loop, and *vice versa*. The main part of the vessel otherwise changes its position very slightly, moving *en masse* in the field, with its course tortuous or straight according to the movements of the eye. In the motion to the right, the loop passes rapidly to the right and is separated widely from the trunk. The opposite holds true of motion to the left. The loop passes and repasses between the observer and the main part of the vessel and its elements appear less amplified but more distinct, thus emphasizing the sensation of depth.

Now discontinue further consideration of these vessels for the moment, change the eyepiece from a one to a one-half inch, move the visual axis slowly up and down, and you will observe another system or layer of vessels that differ in no way from those first described, except that they are dimmer in outline, of

larger calibre, contain larger corpuscles, and lie closer to the light; that is, beyond the vessels first described and between them and the light. The general movement of these vessels, moreover, is opposite to that first described, so that when the eyeball is turned upward the vessels move rapidly downward and then ascend slowly toward their original position. This behavior of the two layers of vessels shows that the former lie in the posterior and the latter in the anterior part of the vitreous. Again resort to the one-inch eyepiece and place the eye about one inch from it. Then will be observed another image that differs entirely from those already described. It consists of an irregular stellate arrangement of fibres or markings that have no resemblance to vessels, and which contain no corpuscular bodies.

Fig. 12. This image is stationary and lies between the light and the last-described vessels. This the writer believes to be the image of the lens itself, seen entoptically, showing very accurately the arrangement of its various fibres or layers.

We have thus seen and studied the following structures:

1st. Three layers of the retina: (*a*) the fovea with the image of the cones; (*b*) the capillaries; (*c*) the veins.

2d. A layer of vessels in the posterior part of the vitreous, lying between the light and the observer and internal to the retina.

3d. A layer of vessels in the anterior part of the vitreous, lying between the light and the vessels mentioned above.

4th. The image of the lens lying between No. 3 and the light. Finally, by moving the eye back from the eyepiece a little and gently opening and closing the lids, floating particles of dust can be noted on the surface of the cornea, which with each movement of the lids move between the lens and the light.

Are these floating structures containing corpuscles vessels? If so, they must be one of two kinds, blood-vessels or lymphatics. That they are not blood-vessels is quite evident from the one fact that no circulation can be definitely discerned. If they are lymphatics, they are specialized to the vitreous and differ greatly from the beginning radicals of this system in the more solid tissues of the body. Indeed this might be expected of vessels that float more or less freely in the body they are designed to nourish. Blood moves in the capillaries about six or nine millimetres per second. This is estimated to be several hundred times slower than in the arteries. Lymph, in the largest vessels, moves about 4.5 mm. per second If it can be said that this stream is several hundred times faster than in the lymphatic capillaries, this, in connection with the fact that the vessels are usually moving and must be studied by indirect vision, may account for the statement that no corpuscular movements can be definitely noted. The blood after death largely leaves the capillaries. This no doubt holds true of the lymph also, and especially here in the eye as the blood pressure is removed and the tension of the eye is diminished, which condition would favor the transudation of both the lymph plasma and the corpuscles, it being probable that in the living normal vessels the leucocytes do not undergo amœboid motion.

The writer has endeavored to demonstrate these vessels, with their contained corpuscles, in freshly removed eyes, by the usual methods of injecting lymphatic capillaries, but thus far with negative results. If these observations are correct, the following conclusions may be deduced from them:

1st. That the so-called muscæ volitantes are normal to every eye, and become annoying only when there is sufficient bunching of vessels to offer noticeable obstruction to light rays.

2d. That they are not due, therefore, to hemorrhage, diseases of the retina, choroid, or ciliary body.

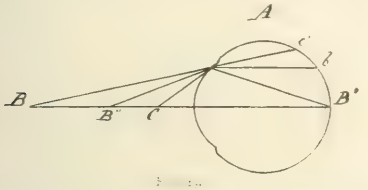
3d. That the felted fibrillæ containing bright spherules described by Retzius and others are in a measure due to post-mortem changes, the ante-mortem normal condition being that above described.

4th. That in all probability they are the lymphatic capillaries of the vitreous.

5th. That this feltwork of lymphatic capillaries sustains the semifluid vitreous substance.

It may be asked: How is it possible to demonstrate vessel walls and corpuscles in the vitreous, when the same cannot be demonstrated in the retina? When a persons looks at a pencil, light radiates from every point on the pencil, and the rays, focussed upon the pigment epithelial layer of the retina, form a true image. The size of this image is inversely proportioned to the distance of the object from the eye. Thus, the farther away the pencil is, the smaller the image, and *vice versa*. In viewing an object entoptically, however, a different principle is involved. No light emanates

from the object itself, but it comes from a luminous point inside the principal anterior focus. The rays that proceed from this point, therefore, are too divergent to be brought to a focus beyond the cornea, but still continue diverging to infinity. Therefore any object lying between the percipient element of the retina and the source of light will obstruct these rays, and instead of a true image an upright shadow will fall upon the retina. The closer the object to the light, the greater the shadow; the nearer to the retina, the smaller the shadow. The vessels and corpuscles in the anterior part of the vitreous should, therefore, be amplified in the shadow, while those that lie closer to the retina should be less so. The entoptical study of the ocular tissues verifies these statements. Fig. 13



illustrates the proposition. Let *A* represent a schematic eye with a single refracting substance; *B* and *B'* the visual axis—*B* the near point, *B'* the principal posterior focus. Light rays emanating from *B* will, by the aid of all the powers of accommodation, be focussed at *B'*. Let the light be brought gradually closer to the cornea, and their point of reunion recedes farther from the principal posterior focus until a point is reached where the rays are practically parallel, *b*. The posterior focus will then be infinity. The anterior luminous point, *B''*, is called the principal anterior focus. Now bring the light still nearer the cornea at *C*. The incident rays now become so divergent that the refracted rays *c'* do not reach parallelism, but continue diverging to infinity. Any object, therefore, that lies between the light and the retina will cast a shadow inversely proportionate to the distance of the object from the light. The nearer to the light, the greater the shadow on the retina and *vice versa*.

The difference in brightness of the corpuscles is probably due to the great flexibility of the vessel, allowing some corpuscles in a single vessel to be nearer and others farther from the retina. If the whole vessel were absolutely on the same level, we should expect the corpuscles to show equally well.

A SUGGESTION IN THE TREATMENT OF DIABETES.[1]

BY G. W. MURDOCK, M.D.

[illegible], N. Y.

I MAY state in the beginning that in presenting, as I intend to do, some brief notes of a case of diabetes I am fully aware of the liability of error in making deductions from the result of a single case. Knowing, however, as we all do, the extraordinary fatality of this disease in the young subject, I think that any method which will arrest it in even one such case is at least worth consideration.

To dwell a moment upon the average prognosis: Pavy says that he has not personally seen the recovery of a patient under twenty years of age. Lauder Brunton says: "When the disease occurs in patients under the age of twenty, few, if any, recover." Dr. Purdy says: "Under twenty years of age the disease is very fatal. Indeed, few recoveries are recorded." Many other authors might be quoted to the same effect.

The salient points of the case that I wish to present are as follows: Upon June 26, 1896, I was consulted by a lad of nineteen, who stated that for some weeks he had noticed that he was passing too much urine. He considered himself strong, had always a great appetite, and was a large meat eater. He had been under my care before with a troublesome dermatitis, and I had found it necessary to cut down his supply of meat very largely before I could cure it. I found that he was passing about six pints of urine daily. The first specimen gave a specific gravity of 1.040 and was loaded with sugar. He had lost a brother with diabetes, at nearly his own age, which added, if it were possible to add anything, to the gravity of his case.

I will not enumerate the details of treatment during the next three months. I did what is ordinarily done. I put him on the diabetic diet, and did my best, as we generally do, to arrange a sufficient variety, so that he should have enough to eat, such as it was. I tried one after another, alone or in combination, many of the best-known medicines, and the result was just about as it usually is in these cases. His urine was diminished in quantity, and the specific gravity fell to an average of about 1.302, but the sugar was always to be found, and he was evidently losing ground in spite of treatment—losing in weight, in strength, and in ambition. At that time I had privately little hope of any but a fatal termination, and I then determined upon a radical change of treatment in some way. While looking up the literature of the subject in search of new ideas, I was struck by a passage in Dr. Purdy's monograph, which I will quote:

"The beneficial effects of temperate eating in diabetes were prominently illustrated during the siege of Paris, as Bouchardat tells us that sugar entirely disappeared from the urine of diabetics, in whom up to that time it had persisted, even although they had been living on a carefully regulated diet."

Dr. Purdy accompanies this with some remarks on the evident value of temperate eating, but seems to me hardly to follow the proposition out to its logical conclusion. I reasoned that if semistarvation did such good, why not adopt it in practice? Instead of trying to find things that our patients can eat freely, why not cut the supply down to the strict necessities of the system? Acting upon this, I reduced my patient's diet list thirty-three per cent. at one stroke, without changing its quality or giving any new medicines. This was upon September 24, 1896, and it was followed by immediate improvement. In four days the urine became for the first time free from sugar, and it remained so for two weeks. Frequent slight relapses occurred, however, always traceable to imprudence in eating, until January 1, 1897, when I made a still greater reduction in his allowance of food and brought him down to the point of being ravenously hungry pretty much all the time. Under this regimen, improvement has been steady and great. Sugar disappeared at once, and has reappeared but twice since for brief intervals, each time being due to overeating. He lost a few pounds in weight at first, under the reduced food supply, but has now regained it and appears as well as ever. His appetite is very keen, but it is not the insatiable one characteristic of the disease, and he has now no unusual thirst. He passes now about forty ounces daily; specific gravity, 1.020 to 1.028.

How long this regimen will have to be continued I cannot tell, but probably a long time, with very cautious trials of more food. He is now allowed twelve ounces of meat daily, and six ounces of toasted white bread, with a small amount of selected vegetables and

[1] Read at the [illegible] annual meeting of the [illegible] Branch of the New York State Medical Association, held in Brooklyn on May 25, 1897.

fruits. He is taking some medicine, but rather as a placebo, and none that I had not given him before without notable result. Perhaps it will not be easy to carry this treatment out in every case, but if a young fellow clearly understands what depends upon it he will generally go through it pretty faithfully. My experience is that the more things we give our patients to do and to take, the more highly they esteem us.

I conclude then that the regulation of food with respect to quality only is not enough in diabetes. It seems to me that a diabetic's digestive and assimilative apparatus may be roughly compared to a mill which from some defect will grind certain kinds of grain better than others, but will grind well only a small quantity of any kind, and clogs up if it is fed too rapidly. If this reasoning is correct, we should, as I have said before, select the most favorable kinds of food, and then limit the supply to near the lowest point possible. It goes without saying that this doctrine will not be universally accepted. I saw an article in a prominent journal a few days ago, in which the writer argued against any restriction in diet, averring that it was useless, and therefore unwise. This is only one more illustration of the differences of opinion which men with practically the same sources of information will hold. I regret that I can report only a single case, but it chances to be the only one that has been under my personal care since adopting this line of treatment. Whether it would be successful in diabetes of advanced life I cannot say. I somewhat doubt if it would be so, but as the disease is then less fatal it does not so much matter. This case is still under treatment and observation, but I see no reason now why it should not go on to full recovery, and I have thought it worth presenting, even if incomplete.

RHINITIS ATROPHICA FŒTIDANS IN ITS RELATION TO DISEASES OF THE ACCESSORY SINUSES.[1]

BY THOMAS J. HARRIS, M.D.,

NEW YORK,

ASSISTANT SURGEON OF MANHATTAN EAR AND THROAT HOSPITAL; INSTRUCTOR IN DISEASES OF NOSE AND THROAT, NEW YORK POLYCLINIC MEDICAL SCHOOL.

Of the numerous forms of disease which present themselves to us as specialists, none is more annoying in its symptoms or more baffling in its results as regards complete cure than that form known to us as ozæna. Discussion of its true nature has engaged the attention of the best rhinologists for many years, without any settlement of the vexatious question. Nor do I come this evening with any idea of offering a settlement, nor, indeed, can I lay claim to do more in what is to follow than to state briefly the results of some of the more recent investigations on this subject. This paper will consist largely of a statement of the views held by Ludwig Grünwald.[2]

At the outset a clear understanding of what is today regarded as ozæna is in order. Ozæna may be defined as a peculiar individual disease of the nose, characterized by a chronic course and by the three symptoms of atrophy of the mucous membrane as well as of bone, secretion forming in crusts, and odor.

The common view, then, is one of an individual disease. This Grünwald strongly combats. He first states the inconsistencies in this theory. We find, first, conditions of atrophy and secretion, but without odor. This difficulty has been met by describing a disease, "rhinitis atrophica sine fœtore." Then it is the experience of every gentleman present to meet with cases presenting hypertrophy in certain spots next to well-defined atrophy. This is commonly met by the theory of B. Fränkel, that a condition of general hypertrophy has at first existed. A distinguished member of the section has, however, stated that he has never met a single case in which he could discover the previous hypertrophy, and to this statement I think we will all give our assent. With a definition such as given above, there is no proof that the same cause lies at the bottom of the atrophy and of the stinking crust formation. Any assertion like this permits the natural inference that the secretion proceeds from the diseased mucous membrane alone. This certainly is a deduction without proof. Even if we admit that the same actual conditions are met with, we have still to prove that these are the chronic causes of the picture and not accidental or consecutive appearances.

The consideration of each mark regarded by different authorities as characterizing the disease falls into two questions:

1st. Is this sign constant in all cases?

2d. Is there proof that the condition of the nose at the present time is the cause of the other appearances?

The results of the microscopic examination by different observers do not agree. Gottstein found in two cases fibrous degeneration of the mucous membrane, with partial infiltration and atrophy of glands and normal epithelium. Krause believes in the actual change of the epithelium into pavement cells and the accumulation of fat cells. Schuchardt found cicatricial disappearance of the mucous membrane. Seibert lays emphasis on the change from cylindrical into pavement epithelium and a cornification and decomposition of the raised-up lamellæ; while B. Fränkel, after seeing this cornification in many cases, found it absent in two. Finally, Réthe rests the nature of "ozæna" in changes in the glands and in fatty degeneration. Any uniform anatomical picture cannot be established from these investigations.

Secondly, the sum of all the conditions discovered in the nose does not answer our second question. The assertion that the altered mucous membrane gives rise to an altered secretion—namely, the characteristic malodorous crusts—is only an assertion. Authorities differ. E. Fraenkel regards the crusts as the products of an abnormal chemical synthesis of the secretion of the anatomically altered gland elements, and denies a purulent secretion of the atrophic mucous membrane; while Zuckerkandl, without giving any proof, speaks of a purulent nasal catarrh as the cause of the atrophy.

No single microscopical result proves to us that the secretion present proceeds from areas found altered, nor is it against the possibility that the deposit of secretion on the mucous membrane causes secondarily the change.

Grünwald next considers some of the common theories of the origin of ozæna.

I. The bacteriological theory: Loewenberg, in his "Kokko-bacillen," found a constant bacillus of ozæna, but proof that it caused the atrophy or crusts is lacking; nor did he once succeed in getting the odor in his cultures.

II. The heredity theory has many supporters. Many gentlemen here have seen whole families affected. That this is far oftener not the case we fail to bear in mind, and, if this were the case, proof of a genuine atrophy is still lacking. Further, Grünwald found, in five cases of ozæna in blood relatives, pus centres, chiefly in the accessory sinuses in each instance.

As a further proof of this heredity theory, Hagemann has asserted that he has found in all ozæna cases an abnormally short diameter of the septum from the nasopharynx to the tip of the nose, and an abnormally

[1] Read before the section on laryngology on the New York Academy of Medicine, May 26, 1897.

[2] "Die Lehre von Naseneiterungen," page 41 *et seq.*

deep nasopharynx. Grunwald has found that the deductions, however, differ according to the particular nationality investigated. Further, it is not the depth of the nose but its abnormal width which interests us; and we see abnormally wide noses with no malodorous crust formation, and narrow nostrils with such crusts. As regards the contention that in connection with ozæna a healthy condition of the adjacent regions is found, and therefore the atrophy must be primary, it is to be said that often the original causes of the atrophy vanish. In proof of this, the author cites two cases of marked atrophy with crusts associated with adenoid tissue, in which all crust formation and secretion disappeared after removal of the adenoids, but the atrophy remained. We can correctly speak of genuine atrophy only when an atrophy of the mucous membrane at a given time was followed at a later period by a deposit of crusts. This has never been shown.

The author now proceeds to study the question more carefully under the following three heads:

1. From where does the secretion proceed?
2. Why does it possess this offensive odor?
3. Why has it the form of crusts?

(1) Whence the secretion? With the exception of Michael's theory that it proceeds from the sphenoidal sinus, all authorities have agreed up to this time that it must come from the mucous membrane of the nose. Gottstein and Juratz assert that they have witnessed it born *in situ* in the form of minute globules. Grünwald states that after the examination of many cases he finally succeeded, as he thought, in discovering one case in which this occurred. More careful examination showed that this secretion proceeded out of both frontal and maxillary sinuses. Other observers had been undoubtedly deceived. A phenomenon had occurred similar to what can be daily seen in certain urinals washed with a flow of water. But as positive proof of this statement, one has only to tampon thoroughly all avenues of approach into the nose from the sinuses, to find a cessation of the secretion.

But the chief argument of all believers in the origin of secretion from the mucous membrane has been that autopsies by various observers have shown no serious trouble in cases of ozæna. Grünwald, disregarding quoted statements, has consulted the original reports in each case, and at length reviews the different cases as reported: Hartmann, one case; Krause, two cases; Fraenkel, six cases; Zuckerkandl, four cases; Harke, six cases.

As a result of his labors, fifteen cases of ozæna and one case of rhinitis atrophica sine fœtore are given in detail. Of these sixteen cases, eleven cases are shown positively to have had involvement of the accessory sinuses. Of the five remaining, in one the condition of the important accessory sinuses is not mentioned. In four the condition of other important areas, as of the nasopharynx, is omitted.

Turning now from any further consideration in this direction, the author rightly claims that the only positive proof is this: If the secretion is from the diseased mucous membrane, treatment of diseased areas elsewhere cannot possibly effect any cure. On the other hand, if disease of the latter is the true cause and involvement of the mucous membrane is only secondary, relief of secretion from these diseased areas must relieve the secretion. In line with this assertion, Grünwald makes the important statement that in the past five years no case of ozæna has been seen by him which did not fail to show some disease or diseased areas elsewhere than in the nose. A series of twenty-five cases is then given *in extenso*, showing in each sinus involvement or involvement of the nasopharynx. Of these, ten show complete cessation of all secretion under proper treatment of the diseased area, and nine show disappearance of odor with a change from crust formation to fluid secretion. These nineteen cases can positively be asserted to be due to focus disease. Three cases of the remaning six were not treated, and three he will not positively declare to have focus disease.

The great point for consideration rests on the question: Are these foci of disease the sole source of the secretion, or are they, as Zuckerkandl asserts, secondary to inflammation and disease in the nose? If the latter is the case, the secretion in the nose continues when the foci of disease elsewhere are healed. This in ninteen of the twenty-three instances was not the case. Therefore it can be justly stated that in these nineteen cases the mucous membrane, without the participation of the treated foci, had nothing to do with the secretion. If now we add the remaining six cases in which the conditions are so probable as to permit them being included, it can be asserted that it is proved that, for Grünwald's cases at least, the discovered foci of disease were not accidental but actual causes of the disease.

Bresgen then is quoted, who in eleven cases of ozæna found foci inflammation in every one. At the same time the author meets a very plausible objection suggested by Réthe's report, who in sixty-four cases found only two cases of sinus disease. The result will correspond with that obtained by many of the gentlemen present this evening. Grünwald's explanation is the great difficulty in the diagnosis of sinus disease in many instances. In his judgment many observers even to-day are overlooking sinus disease, just as a few years ago it was universally regarded as a most rare affection. He adds that in the last two years he has himself treated two cases for a year's time unsuccessfully before he recognized the presence of sinus disease. He gives the history of a case illustrating this difficulty in his own practice.

In conclusion, as a result of all these facts, he declares, on this first point of the origin of the secretion: 1st, that its origin from the mucous membrane of the nose is not at all proven; 2d, on the contrary, that proof of the origin from foci of disease in adjacent areas has been positive in a large series of cases. In another series the probability is very strong.

(2) Why does the secretion possess the peculiar odor? Grünwald is strongly of the opinion that the cause is purely mechanical. In proof of this, he states that those conditions the removal of which cause a disappearance of the odor must be the cause of the odor. These conditions are varied. In ten cases the establishment of free drainage for the pus removed the odor; here decomposition due to retention was the factor. In two cases removal of adenoid tissue served the same result. In one case the odor disappeared after a sequestrum was removed. In three cases it depended on crusts which continually reformed; in these three cases the fluid pus, as it proceeded from the sinus opening, was odorless.

The important question naturally suggests itself: What shall we say of those cases of atrophic rhinitis without odor? Here nature has given the same aid in establishing drainage that the surgeon does. Odor existed previously, but all sequestra have been removed or roomy openings from the sinuses have been produced by the atrophy. Syphilis even is not to be excluded in this ruling. Granted that the odor of syphilis of the nose is intense, it is due only to necrosis in the nose or neighboring sinuses. With removal of sequestra and widening of the nares the odor ceases, as we know. In a word, when disease of bone exists, or secretion is retained in enclosed cavities or in nares with roomy recesses, we may look for odor. In cases in which it does not exist with crust formation, the nostril is favorably formed by nature at birth or in self-healing for an easy voiding of the crusts. The fact that

the fresh secretion has no odor is proof that bacilli begin to exist only as a factor of decomposition.

(3) As regards the question of the form of crusts which the secretion assumes: This is regarded as purely dependent on a physical condition, lack of water, and that they cannot be blown out because they are too tenacious.

As a result of these observations, the following inferences are drawn:

1. An individual pathological-anatomical picture attended by malodorous crust formation in wide noses does not exist.

2. Any hereditary or anatomical disposition producing a condition called ozæna does not exist.

3. In general, any peculiar inflammation of the nasal mucous membrane producing odor with crusts and atrophy is unproven.

4. The existence of a genuine atrophy is unproven.

5. That all cases of malodorous crust formation rest on sinus empyema is refuted.

On the contrary, it is proven:

1. That in a series of cases carefully studied, the secretion proceeded from foci of suppuration in various manners.

2. That the formation of crusts as well as of odor arises under different conditions.

3. That both conditions often occur together, but often each by itself, and as well with as without atrophy of the mucous membrane.

As a deduction of this we must conclude that the name ozæna has no correct usage save in a symptomatic sense.

We have thus in a hurried manner attempted to abstract Grünwald's earnest arguments. Great thanks are due him for his laudable scientific work on a subject so baffling to the whole school of rhinologists. What avail our many plans of treatment, our ever-growing list of new drugs! Nature in time cures these cases, but do we? What can we honestly claim in the vast majority of our cases as a result of treatment but cleanliness, and thus relief as long as treatment continues? Who of us by any line of treatment can point to seventy-four per cent. of our cases cured, as does Grünwald?

Before proceeding to examine a little in detail his arguments, a slight reference to some of the other more recent theories is in order. Many of them, as those[1] of Loewenberg, Fränkel, Krause, and Taufel, have already been referred to. The views of Bosworth, who regards ozæna as dependent on a purulent rhinitis of childhood, are well known to us and correspond in the main to the position held by B. Fränkel.

Berliner[1] believes that an abnormal enlargement of the middle turbinated with contact with the septum, causing a damming up of secretions with altered blood conditions in the spheno-palatine foramen, is the cause. That there is truth in this theory in certain instances is undoubted. In the large majority of cases, however, we believe the contact acts mechanically to hinder free escape of pus. Watson,[2] without proof, regards ozæna as a form of lupus; while Mackenzie[3] thinks the atrophy is the result of the pressure of the crusts. But whence then the crusts?

The most important communication, however, is by Abel.[4] In a very exhaustive article Abel claims in one hundred cases, previously diagnosed by a clinician as ozæna, to have found a bacillus which he calls the "ozæna bacillus." This he regards as the same as the bacillus of Loewenberg and similar to the pneumococcus of Friedländer, but with distinct differences. He regards ozæna as an infectious disease which soon causes changes in the mucous membrane. Whether hypertrophy followed by atrophy is the case is uncertain. In any case atrophy is the final stage. He regards the odor when present as the result of a bacillus yet to be isolated, for ozæna with the presence of the "ozæna bacillus" occurs without odor. In one case he succeeded in originating the disease in an individual by introduction of the bacillus.

In five hundred and fifty cases not ozæna examined by himself and by Paulsen, an independent Italian observer, no "ozæna bacillus" was discovered. Others have claimed to discover this bacillus in healthy throats and noses. Either they were mistaken and it was the Friedländer bacillus which so closely resembles it, or the seeming normal nostril on careful examination will reveal a chronic catarrhal process, the first stage of ozæna. Finally, the bacillus will not alone cause the disease. Certain other reducing causes are demanded in addition.

When now we come to consider Grünwald's arguments, we are compelled to admit that they are very reasonable in the main. He has certainly refuted one of the chief objections to his theory when he shows that the result of the various autopsies in cases of ozæna is not to prove the presence of healthy sinuses. It will be observed that he does not claim disease of the sinuses is alone the cause, but what he designates focal disease; that is, areas of suppuration elsewhere than in the nose. The whole contention in my judgment rests on whether such a disease as genuine atrophy ever exists. Most of us who have been observing our cases carefully must concede the important rôle of sinus disease in a large number of instances, and adenoid growth each one of us present has recognized as a cause, but can we regard these as the sole causes?

1. Grünwald admits, as to his series of twenty-six cases, that six or twenty-six per cent. cannot be proved to be due to sinus or focal disease.

2. Again, consider the number of cases of sinus disease we meet without atrophy or crusting with odor.

3. It is true that the difficulty in the diagnosis of sinus disease is at times great, but many competent observers have failed to recognize such a proportion of sinus disease in their ozæna cases as does Grünwald. It is scarcely possible that Réthe could have erred to the extent of finding only two cases in sixty-four.

4. Grant, too, that it is not proven, is it reasonable to assume that in no instance does a disease of mucous membrane originate secretion?

5. Grünwald further in his enthusiasm pushes his objection to the anatomical investigation. While there are certain differences, the reports of the best necroscopists in the main agree regarding the condition of the mucous membrane.

6. And are we not going too far to affirm that every case of ozæna in children possesses "focal disease"?

7. To my mind, however, the strongest proof against the Grünwald theory of no genuine atrophy is found in Abel's investigations. Grünwald felt he could brush aside Loewenberg's uncertain work. This cannot be brushed aside. One hundred cases of ozæna showing a bacillus constantly, and five hundred and fifty cases not ozæna not showing it, means something, and to my mind is strongly suggestive of furnishing proof in connection with constitutional and anatomical defects for the existence of a genuine atrophy in certain cases, attended by secretion forming itself into crusts due to physical causes.

My own series of cases is so far quite limited. In ten cases I find the following results:

Case I.—Aged twenty-eight. Duration, four months. Ethmoiditis, etc.

Case II.—Aged twelve. Duration, many years.

[1] Deutsche med. Wochenschrift, 1889.
[2] Lancet, 1890.
[3] Brit. Med. Jour., 1895.
[4] Zeitschrift für Hygiene, 1895.

Double ethmoiditis. Operation relieved odor. Sister, aged four, similarly affected.

Case III. — Aged twenty-one. Duration, four years. Occasional pain in frontal sinus; both middle turbinals polypoid; pus on anterior portion.

Case IV. — Aged nineteen. Duration, fourteen years. Double ethmoiditis.

Case V. — Aged twenty. Duration, five years. Much odor, atrophy, and crusting; empyema of left sphenoid, with ethmoiditis. Operation.

Case VI.—Duration, twenty years. No sinus trouble.

Case VII.—Ethmoiditis, etc.

Case VIII. — Aged twenty-two. Duration, ten years. Adenoid growth.

Case IX.—Aged thirty-five. Duration, fifteen years. Much atrophy, free discharge, no odor, no sinus disease.

Case X.—Much odor and crusting; necrosis of septum; syphilis.

This shows that out of the ten cases five possess sinus disease, one has associated adenoid growth, one is due to syphilis, and three do not show any involvement of the sinus. The six cases of focal disease are still under observation, so do not permit of any final report as regards the result of the operations at this time, though they were greatly benefited. While this series is quite small, it is significant as being in line with Grünwald's result—seventy per cent. showing involved sinus disease.

As a result of these considerations, we feel forced to conclude:

1 That there is no single constant cause for ozæna. Ozæna is rightly to be regarded only as a symptom.

2. That a genuine atrophy until recently unproved, from Loewenberg's studies confirmed by Abel and Paulsen, in all probability does exist.

3. That focal disease, including especially disease of the accessory sinuses, while not the only cause, is a very important and common cause.

4. And as a most practical conclusion for the rhinologist, each case of ozæna, in addition to being treated with the proper constitutional and local measures, is to be thoroughly and repeatedly examined for evidence of such sinus involvement.

BLUEWEED: CHEMICAL AND PYSIOLOGICAL NOTES.[1]

By AUGUST DRESCHER, A.B., Ph.G.,

NEWARK, N. J.

Some time in January last, the writer was asked by Prof. Phil. E. Hommell (one of our active members) to make an examination of a specimen offered at the time, said by Professor Hommell to be derived from the common "blueweed" (Echium vulgare; natural order Boraginaceæ). Dr. Hommell was inclined to attribute pharmaco-dynamic virtues to this plant, and wished me to search for alkaloids. A well-mounted specimen of the plant will be presented for your inspection by Dr. Hommell, together with the botanical description, while I will here confine myself to the account of the chemical and physiological laboratory doings.

The sample handed to me, being in good condition, weighing a little over ten grams, was coarsely powdered and treated as follows:

Preliminary Examination.—One gram was macerated with Prollius' fluid modified (*vide* Dr. A. B. Lyons' work on drug assaying). The filtered fluid, after evaporation having next been shaken out with water acidulated with H_2SO_4, was now subjected to the group tests: (1) Potassium iodide + iodine (Wagner); (2) potassio-mercuric iodide (Mayer); (3) tannic acid.

Tannic acid gave only a faint precipitate.

Dragendorff's regular scheme, alternating with the various solvents in acid and alkaline solution, was then applied upon five grams of the sample, the results showing presence of chlorophyl, wax, fat, and resinous and gummy matter. The mineral ash was not estimated.

The sublimation test (between watch glasses) was negative—absence of salicylic and benzoic acids, volatile alkaloids, and other volatile matter.

The bulk of the extract, prepared as above, was now divided into two parts, (*a*) for chemical tests, (*b*) for physiological tests. The watery solution, acidulated with H_2SO_4, upon evaporation assumed a purplish color, which upon dilution vanished. After it had been shaken out with benzol, and the evaporated residue tested with potassium bichromate + H_2SO_4, no play of colors was observable (absence of strychnine, etc.). The concentrated residue, however, gave the reaction quite distinctly, which would indicate "curarine" (this not being soluble in benzol, while strychnine is). The best solvents for curarine are given by the authors cited as alcohol and water, while in chloroform and carbon bisulphide it is claimed to be almost insoluble, as well as in benzol, etc. Strychnine, methyl-strychnine, etc., are insoluble in water, but more or less soluble in the other fluids. The color reactions of the purified residue obtained by the writer were, with nitric acid, purple, and also with H_2SO_4; with potassium-bichromate + H_2SO_4, the above noted "play of colors."

This, the chemical work, being in itself not entirely satisfactory, physiological experiments were considered as absolutely necessary and truly decisive. In inorganic analysis, on the other hand, if skilfully conducted, the results seldom, if ever, need to leave a doubt as to the nature of the object under consideraton, as we all know.

Physiological Tests.—Being well acquainted with Dr. Vet. Med. Otto Leis, a recently graduated, talented young practitioner, with a thorough clinical experience at the New York Veterinary College, I asked him to assist us in this interesting work. The results:

Dr. Leis into a young guinea-pig (weight, ½ lb.) in good health injected hypodermically twenty minims of the clear water solution prepared by me. After two minutes, eye dilatation was excessive; after three minutes, paralysis of hind joints, rapidly progressing; convulsions appeared at intervals, of a "clonic," not a "tonic" kind; no tetanus; no rigidity of muscles (even one-half hour after death). Difficulty of breathing; gasping; death in twenty-four minutes (from asphyxia), the body remaining quite limber; slight nose bleeding. The post-mortem examination showed no signs of organic lesion. The urine, removed from the bladder after death, immediately and completely reduced an equal volume of Fehling's solution on boiling.

Résumé and Notes.—The results of these investigations would seem to point to three possibilities, thus: methyl-strychnine, curarine, or picrotoxine.

The literature on Echium vulgare is scant. Husemann, "Die Pflanzenstoffe," quotes a work by Buchheim, published at Giessen, 1870, "The Pharmacology of Curarine" (as found in Echium).

Curarine was first prepared by Preyer in 1865 in crystal form from commercial curare (the South American arrow poison). The three above-named substances have analogies in common—similar crystal form, chemical reactions, etc.; but methyl-strychnine

[1] Contributed to the New Jersey Pharmaceutical Association at its annual meeting at Princeton, N. J., May 5, 1897.

produces tetanus (though otherwise differing from strychnine). Curarine has not been observed to induce rigidity of the muscles and true tetanic convulsions.

Picrotoxine, treated with nitre, H_2SO_4, and NaHO in excess, gives a brick-red color. Authors differ somewhat as to the chemical and even the physiological properties of curarine (*vide* Allen's "Organic Chemical Analysis"), even Allen attributing to it a tetanic effect; in the case under consideration such action was not observed.

Although the watery extract of our sample exerted such a deadly activity, it was, in spite of the most earnest efforts, found impossible to isolate a single pure crystal. The oily droplets finally remaining could not be bought to crystallization in the desiccator over H_2SO_4. In the summer with new material, the work may be continued. If this alkaloid (?) should turn out to be a remedy against hydrophobia, etc., the pains taken in preparing it would be handsomely rewarded.

Progress of Medical Science.

Nature and Treatment of Tetany. — Dr. Oddo (*Revue de Médecine*) shows that the theory of the etiology of tetany has an important bearing on its treatment. In children he does not think it due to rickets, though rickets may favor the appearance of tetany. He thinks that the nervous symptoms are caused by a form of toxæmia due to the absorption of poisonous bodies produced in the gastro-intestinal canal. The form of indigestion most likely to lead to tetany is that attended by dilatation of the stomach and long retention of the food. Tetany in the adult is believed to be connected with a special form of indigestion, attended by hypersecretion of the gastric juice containing an excessive quantity of hydrochloric acid. Kassowitz objects to this theory, since dyspepsia is very common in children and tetany is relatively rare. Oddo replies to this objection by saying, 1, that for the production of tetany it is probably necessary that there should be some special form of perverted digestion possibly associated with some form of microbe, or some peculiar condition of the gastric secretion; 2, that for the production of tetany there is necessary a special vulnerability of the nervous system. He would not have tetany accepted as essentially a disease of the nervous system, but that a special form of toxæmia causes its characteristic effects only when there is a predisposition in the nervous system. He notes the fact that Weiss in the adult, and Bonome and Cervesato in children, have described certain lesions of a degenerative nature in the gray substance of the spinal cord, most pronounced in the anterior horns in cases of tetany. Beginning with hyperæmia and swelling, they go on to degeneration of the cells, with overgrowth of the neuroglia. As to diagnosis, he does not accept the opinion of some of the German writers that laryngeal spasm is pathognomonic of tetany. It is frequent in children under two years of age, and as it may cause death the early diagnosis of tetany is important, for much may be done to remove the cause underlying the nervous instability. Among the less common manifestations of tetany are retraction of the head and squint, which may lead to the diagnosis of meningitis. In meningitis the tetanic spasms of the hands and feet are seldom present, vomiting is more persistent, and constipation is the rule; whereas in tetany there is nearly always diarrhœa. In tetany the pupils are not unequal and the pulse is frequent. In the treatment of tetany the two objects are to expel the toxic substances and to prevent their formation. Both indications are met by calomel, which should be given every other day in doses of three-fourths of a grain or more according to the age of the child. Washing out the stomach is beneficial, provided care is taken to avoid the risk of exciting laryngeal spasm. Any errors in the diet of the child should be corrected. If there is a deficiency of acids in the gastric contents, hydrochloric acid should be given after each feeding; if an excessive amount of acid is present, a small dose of sodium carbonate or lime water should be administered. He recommends, in addition to calomel, benzonaphthol, which may be combined with subnitrate of bismuth. Boiled water medicated with boric acid may be used to wash out the large intestine. The child should be guarded from cold and excitement. For the immediate relief of the spasms warm baths are very effective. Chloral may be given as an enema to relieve an attack. Bromide of strontium is a good sedative to be used continuously during the tetanic state. If laryngeal spasm becomes suddenly serious, a sponge soaked in very hot water should be applied to the neck, followed if necessary by inhalation of chloroform, which must, however, be used with much care.

The Roentgen Rays as an Aid in the Diagnosis of Thoracic Affections and Lesions of the Respiratory Apparatus.—Drs. Declerc, Oudin, and Barthélemy (*Le Bulletin Médical*, June 29, 1897) publish the results of a series of experiments showing that the radiograph is useful in the diagnosis of lesions of the respiratory apparatus as well as in aneurisms of the aorta inaccessible by auscultation and percussion The first tests were made before and after thoracentesis on a patient having an abundant effusion of the left pleura. The opacity of the effusion was clearly shown, its superior limit, and the return of the transparency of the pulmonary tissue after puncture. It is shown that the thoracic aorta at its union with the aortic arch is dilated and projects to the left of the vertebral column, at the point of the fifth dorsal vertebra, as is observed in most subjects in whom the peripheral arteries are hard and sinuous. Another radiograph of the thorax of a child affected with adenopathic tracheo-bronchial tuberculosis shows, besides a ganglionic mass behind the sternum accessible to the ordinary means of examination, profoundly situated in the thick part of the lungs, around the hilum, numerous and voluminous ganglions especially at the right and extending the length of the bronchial ramifications. A fourth picture, showing the thorax of a tuberculous patient with right pneumothorax, reveals the pleural cavity filled with air and so transparent, especially in the space between the base of the retracted lung and the surface of the purulent effusion, that at this point the bodies of the vertebræ can be distinguished, with their fibro-cartilages and the articulations of the neighboring sides. An opaque zone limited above by a horizontal line corresponds with the purulent effusion and fills the entire right costal diaphragmatic sinus. The diseased lung, diminished in volume and retracted toward the hilum, appears distinct; one can see its rounded apex, its external oblique edge, its slightly concave base, and an adhesion from its base to the wall. One can measure its exact volume, its form, its dimensions, its situation in the thoracic cavity. It is probable that repeated examinations of the same patient would enable one to measure the variations of the effusion and detect all the changes which are produced in the size and form of the lung. If the perforation becomes cicatrized and if reabsorption of the intrapleural air by the lung takes place, and if the lung approaches its wall, all would be shown before auscultation would reveal it. The left lung in this patient was supposed to be healthy but

showed bronchial râles in the upper half; it was the seat of profound tuberculous lesions. One sees here the utility of the Roentgen rays in the diagnosis of tuberculous infiltrations inaccessible by the other modes of exploration. The last experiment gave additional evidence of this utility. A young girl who presented no certain signs of tuberculosis was examined by this method. The right lung showed opacity at the apex in the middle part, that is to say, a profound lesion. Without detracting from the value of the other clinical methods of exploration, the Roentgen method confirms, completes, and sometimes corrects the diagnosis of thoracic affections.

Etiology of Asthma.—Dr. Kuss holds that among the various causes of true asthmatic dyspnœa, the principal one is a defective evaporation caused by a want of sufficient fluid in the epithelial cells of the pulmonary vesicles. This insufficiency of fluid must be attributed to the reflex affection, from various causes, of the vasomotor nerves governing the nutrition of the cells, and produces the same effect as a sudden and considerable reduction in area of the active pulmonary surface. The convulsive action of the respiratory muscles might easily be a consequence of this dyspnœic condition. In the treatment of asthma (1) increased activity must be given to the secretory powers of epithelial cells by acting on the secretory vasomotor nerves; (2) the determining cause of the harmful reflexes must be obviated by various recognized methods; (3) the physiological and anatomical soundness of the alveolar walls should be maintained by appropriate nutrition.

Acute Pulmonary Gangrene with Pyopneumothorax in a Healthy Youth.—Ewart and Sheild, writing in *The Lancet*, June 19, 1897, report the case of a young man, eighteen years old, who came under observation on account of pain in the back and cough. A week previously he had been suddenly seized with a feeling of chilliness and on the following day severe pain appeared in the left supraspinous region, extending downward. A day later there were pain and cough, without expectoration, and great weakness. For the succeeding four days pain and cough persisted, still without expectoration. Sensations of heat and cold alternated. The patient looked ill and complained of weakness. The lips and ears were slightly but distinctly cyanotic. The pulse was 86, the respirations were 36. No cardiac abnormality could be made out. On auscultation scattered râles could be heard on both sides of the chest in front. Posteriorly on the left side there was dulness from the inferior angle of the scapula, with enfeebled breathing and deficient vocal fremitus. Scattered râles were heard on both sides. Pain and fixation of the chest prevented the ejection of sputum. The tongue was heavily furred: the urine was normal; the temperature was 101° F. Broncho-pneumonia following influenza was diagnosticated. The breath, however, became offensive, and a fit of coughing culminated in the expulsion of a large amount of whitish, foul-smelling muco-pus. Later, signs of left-sided empyema appeared. Preparations were made for aspiration, but this was deferred temporarily because the dulness in the left scapular region was replaced by hyperresonance. The occurrence of a limited pneumothorax was suspected, but as the heart was found on careful examination not to be displaced toward the right an alternative diagnosis was made of bronchiectasis with sudden evacuation of the contents of a cavity. Subsequently the cough became troublesome and orthopnœa set in; cyanosis became marked, the pulse rapid, and exhaustion extreme; the temperature rose to 102° F. The apex beat of the heart was now displaced to the right and the upper half of the left side of the chest was hyperresonant, front and back, with obliteration of the breath sounds, while the lower portion was dull. The breath was offensive and the difficulty in breathing was urgent. The conclusion was now reached that a gangrenous lung had ruptured into the left pleural cavity, with the development of pyopneumothorax. Accordingly an incision was made in the sixth left intercostal space behind the midaxillary line, and a large amount of fetid pus and gas escaped. An empyema tube was introduced. The heart immediately returned to its normal position and the general condition soon improved. At the second dressing more fetid pus came away and the discharge continued for some time. After a while the breath sound could be heard close up to the margin of the wound in front and above and also posteriorly down to the level of the incision. Behind and below the breath sounds were not audible and in this area there was dulness on percussion. The left side of the chest had fallen in. The patient had had measles in childhood, but had escaped other illness. The family history was good and without tuberculous taint.

The Surgical Treatment of Intussusception in Infants.—Pitts has reported seven cases of intussusception of the bowel in children between the ages of ten weeks and two years and a half, of which two were of long standing and the remainder of recent occurrence, and all of which were treated by abdominal section, with recovery in six and death in one of the acute cases. Upon the basis of this together with earlier experience it is recommended that, in cases of recent acute intussusception, distention of the bowel by air or water, in conjunction with gentle external manipulation, may be tried under an anæsthetic. The surgeon should, however, be present and be prepared to open the abdomen at once if a satisfactory result is not quickly obtained. In many cases the effect of such inflation is to reduce the main mass of the tumor, but to leave an irreducible portion in the right iliac and lumbar regions. This amount of success aids the subsequent operation and allows the tumor to be delivered easily through a smaller incision and with less manipulation. If inflation has apparently been successful the child should be carefully watched, and with evidence of continued trouble abdominal section should be resorted to and further inflation tried. An exploratory operation should be undertaken without preliminary inflation when, from the severity of the symptoms or the chronicity of the case, there is reason to believe that such inflation would be dangerous or unlikely to succeed. The time required for insufflation adds considerably to the shock. The median incision is suitable in the majority of cases, but when the tumor is in the cæcal region a limited incision in the right semilunar line may be found most convenient. For the reduction of the final portion of an intussusception the tumor should be brought outside the wound, so that the operator may clearly see the condition of the bowel and make sure that the reduction is complete. Thickening about the ileo-cæcal valve may be easily mistaken for an incomplete reduction. When doubt exists an incision may be safely made into the colon and the parts examined from within the bowel. An incomplete reduction will certainly lead to further trouble. In some of the cases of spontaneous cure, or cure by inflation or manipulation, it is highly probable that complete reduction is not effected and the chances of recurring symptoms are therefore greater than after careful operation. In none of the seven cases reported did it seem desirable after reduction to attempt any fixation of the bowel—such as by suture of the mesentery—as a security against recurrence. Such a procedure seemed contraindicated, as it would have added to the length of the operation and

have been uncertain as to the effect produced. All of the children were given small doses of tincture of opium and kept under constant medical supervision for a considerable time after convalescence from the immediate condition. When reduction is found impossible a resection inside the colon would seem to afford the best chance. The junction between the large and small bowel must be made secure before any part is cut away. When gangrene is present the condition in young children is almost hopeless. Complete section and end-to-end union, whether by Murphy's button or by suture, has so far been practically without success. Perhaps rapid resection, with lateral implantation of the small bowel into a healthy portion of the colon, and bringing the cut edge of the large bowel to the surface as a temporary vent for the escape of flatus, would be the quickest and safest method to adopt. Safely, however, as infants withstand a short operation, a prolonged one under such circumstances seems almost beyond their power.—*The Lancet*, June 12, 1897.

Terminal Infections in Chronic Diseases.—Dr. Flexner has published the results of a statistical and experimental study of terminal infections, based on the bacteriological examination of the necropsies of two hundred and fifty-five cases of chronic heart or kidney disease, or of the two combined (*British Medical Journal*). Of these, two hundred and thirteen gave positive, and forty-two gave negative results. The infections may be (1) local—these are far the commoner—or (2) general. In the general infections there was a striking predominance of the usual pyogenic cocci; streptococci were the variety most often present, but were not highly pathogenic for laboratory animals. The usual lesions found were acute splenic enlargement and parenchymatous degenerations in the viscera; in a large proportion of cases visible focal lesions were not present. The portals of entry of the micro-organisms in these cases of general infection could not always be determined. In the local infections the micro-organisms were for the most part the same as in the general infections. The colon bacillus was so frequently found in the kidneys and lungs, and streptococci were so commonly present in congested and œdematous lungs, that these organs must be regarded as specially favoring the growth of these micro-organisms. In the great majority of cases the presence of the colon bacillus was not regarded as of pathological importance; the exceptions were when it was met with generally all over the body and in large numbers, and when it was present together with pyococci. Lists of the micro-organisms found and of their portals of entry are given, and it is seen that the intestine is the portal of entry for many of the bacteria found not only in peritonitis, but also in pleurisy, endocarditis, etc. The statistics show the value of systematic bacteriological examination in routine post-mortem work, and illustrate Osler's remark that secondary infections carry off many incurable cases. In order to throw light on the factors which render a patient with chronic disease so much more susceptible to infection than a healthy person, Flexner examined the bactericidal power of blood serum obtained from cases of chronic disease, and compared it with that of normal blood serum and of placental blood serum. The bactericidal power was tested on cultivations of the staphylococcus aureus. He found that normal blood serum possessed distinct bactericidal properties, and that this power was absent or diminished in at least some cases of advanced chronic disease.

Frequency of Spontaneous Recovery from Appendicitis.—Dr. Rotter states, in his report of the two hundred and thirteen cases treated in the medical and surgical departments of the St. Hedwig Hospital at Berlin, 1893 to 1895, that the mortality in appendicitis is not so large as is usually assumed, amounting in his experience to only 8.9 per cent. of the total number of cases, and to only 2.5 per cent. in the circumscribed cases (*The Journal of the American Medical Association*). He reviews also the results secured by others, especially Sonnenberg, which imparts extra interest to his communication. He is more conservative than Sonnenberg, who advises removing the appendix even in mild cases that begin "stormily," particularly if there is any chronic tendency, stating that mere incision of the abscess is never sufficient. Rotter's practice is immediate operation in diffuse peritonitis, conservative treatment in the circumscribed cases. He does not accept Sonnenberg's seven forms, but divides all cases into the two—general and localized peritonitis. He found that of the localized cases, ninety per cent. recovered spontaneously, and eighty-four per cent. of the total number of cases received at the hospital during the first six days of the attack. He ascribes great importance to the fever, which he classifies into five groups: 1. Cases begin with high fever, up to 40° C.; decrease third or fourth day; rapid convalescence. 2. Begin the same, with fever up to 40° C.; fever lasts longer, but not over 39° C. by fifth day. In fourteen cases of this kind all recovered; three required operation for circumscribed abscesses. In the absence of fever, he operates upon such cases on the ninth day. 3. Same, with temperature over 39° C. longer than the fifth day; grave virulent infection; prognosis unfavorable. In eleven cases there were two deaths; the fever disappeared spontaneously in two cases the eighth or ninth day; four were operated; three patients recovered after a protracted stay in bed (perforation into the intestine). This group requires prompt surgical intervention, not later than the sixth day, and earlier than this with symptoms of progressive peritonitis. 4. After an earlier fall in the temperature it rises again, which always indicates larger accumulations of pus. Four patients of the six in this category were operated upon; one died of general peritonitis, and another left after the third remission, apparently cured. These cases should be operated upon during the first remission. 5. General peritonitis; the temperature is low, often subnormal in severe infection, higher in progressive cases; the pulse indicates the severity of the attack; recovery is to be expected only with surgical intervention. He believes that pus is always present in acute attacks, whether found or not. It may be discharged through the lumen or the perforation and absorbed by the peritoneum.

Retroperitoneal Tumors.—In a recent issue of the *British Medical Journal* is reported an interesting debate bearing on retroperitoneal tumors which took place at a meeting of the Royal Medical and Chirurgical Society, in connection with Mr. Marmaduke Sheild's case of successful removal of a large fibromyomatous tumor arising from the retroperitoneal space. The origin of such tumors may be difficult to determine, as they tend to spread far and wide behind the peritoneum; some may be derived from the smooth muscular tissue which extends from the uterus into the broad ligament, and has, we believe, been termed the uterine platysma; while Mr. Eve suggested that the smooth muscular tissue said to be present at the root of the mesentery might be the starting-point of some fibromyomata. Probably many of the growths described as retroperitoneal sarcomata are, like most "sarcomata" of the breast, allied more closely to soft fibromata than to malignant tumors, as evidenced by the facts that they displace rather than invade adjacent tissues, and do not recur after removal, though that operation may be extremely hazardous from the

extent and size of the growth. The retroperitoneal fibromata may be extremely œdematous or may contain fat, as in Sir Spencer Wells' case examined by Mr. Eve. Occasionally they may be almost or entirely composed of fat, and form enormous tumors, which may somewhat resemble malignant tumors or more closely ascites. From malignant tumors their course and the absence of cachexia distinguish them, while the effects of paracentesis differentiate them from ascites. Mr. Lockwood drew attention to the areas of resonance which vary in their position as a clinical feature of retroperitoneal growths; but this fact, together with fluctuation, met with in fatty tumors, would tend to make the resemblance of ascites and retroperitoneal lipomata all the more close. No wonder, then, that such semisolid growths have been subjected to paracentesis.

Diagnosis of Primary Malignant Tumors of the Pleura and Lungs.—Dr. Zagari (*Arch. Clin. de Bordeaux*, March, 1897) groups the special clinical symptoms as follows: 1. Insidious commencement of the affection. 2. Marked general debility. 3. Absence of fever. 4. Persistent, increasing pain. 5. Circumscribed œdema of the chest. 6. Development of the lymphatic ganglia on one side of the thorax, exclusively or more prominently; possible turgescence of the veins in the anterior and lateral parts of this side. 7. Sweats and more elevated temperature on one side of the thorax. 8. Distress in breathing and more intense oppression than can be ascribed to the quantity of fluid obtained by puncture. 9. Irregular distention of the thoracic cage, especially in the superior and anterior region of the chest. 10. Intercostal spaces neither prominent nor dilated. 11. Complete dulness, without the slightest elasticity, in the superior and anterior region of the thorax; zones of dulness close to zones of resonance. 12. Dulness over the manubrium or the sides of the sternum, which indicates not only the displacement of the mediastinum toward the sound side, but also the irregularity of this displacement. 13. Skodaic resonance over the clavicle and sternum. 14. The laryngo-tracheal murmur distinctly transmitted to the superior regions. 15. Persistence of the plessimetric and acoustic phenomena even after evacuation of the fluid in the pleural cavity. 16. This fluid is very thick, rich in fibrin, hemorrhagic, with histologic elements special to the neoplasm. 17. Peculiar sensation of having penetrated into a compact, deep, thick mass, when inserting the needle. 18. Puncture is without effect, or the fluid forms rapidly again. 19. Displacement of the heart and liver, out of all proportion to the amount of liquid withdrawn.

Lavage in Chronic Gastritis.—Dr. Behrens (*St. Louis Medical and Surgical Journal*, April, 1897), in an article on this subject, summed up the uses to be derived from lavage as follows: Mucus and mucous plaques are washed out, stimulating the cells to secrete a juice that is acid, with no alkalinity to neutralize it. By the direct application of warmth we insure in time muscular reaction, consequently a relief of this atonic or sluggish condition of the stomach, raising the function of this organ to the capabilities required of it. Of the solutions, sodium bicarbonate is preferably used in these cases to facilitate removal of mucus, and when acids other than normal exist causes, to a degree, neutralization. The last washing should be with clear warm water, 110° to 112° F.; afterward the medication indicated may be given to continue stimulation, viz., bitter tonics—preferably strychnine in its various combinations. By testing the contents we facilitate diagnosis in stomach disorders. Lavage should be done about one-half hour before the main meal, to clear the stomach of unnecessary secretions and also to avoid clogging the tube with food from the last meal. Lavage should not be done on those having aneurism, arterial sclerosis, severe valvular lesions, in the later stages of pregnancy (if first introduction of tube causes much distress), œsophageal cancer, gastric ulcer or gastric cancer when there is rapid disintegration of tissue, in those afflicted with spasm of glottis, enlarged tonsils (interfering or causing obstruction to respiration), or the severe asthmatics. Cleanliness must be strictly observed in tube introduction. All solutions being ready and at a proper temperature, a fairly stiff tube is selected; the patient is seated on a firm chair, with strong, straight, high back, and covered with a rubber apron (to prevent soiling clothing by vomitus, etc.), and over this a clean white towel should be laid: the head is tilted slightly backward, the mouth opened about one inch; the tube, being lubricated, is passed directly back; it turns readily in the pharynx with just a little force. About this time the patient gags, and it is necessary to watch that the tube is not jerked out by him. Ask him to swallow: assure him everything is all right (though most patients feel the first time as if they were going to strangle). Then quickly pass the tube to the mark outlined for adults: after a moment's rest have him breathe a few times. Being assured that it has passed into the stomach, pour in about five hundred cubic centimetres of warm water, and the work from this time on is readily accomplished. Patients become so accustomed to its introduction after a few times this it is not looked on with any fear. In many cases of chronic gastritis one washing has been of such benefit that it is not difficult to continue this form of treatment, which apparently seems at first impossible.

Different Varieties of Aortic Regurgitation.—Dr. Handford, at a meeting of the Nottingham Medico-Chirurgical Society, held on March 3d, stated that the chief characteristics of the rheumatic cases were: (1) The disease came on at a much earlier period of life than atheroma, and was the main cause of aortic regurgitation arising between the ages of five and thirty-five years; (2) the arteries were generally sound; (3) the heart muscle was comparatively sound; and (4) apart from fresh attacks the valvular disease soon ceased to be progressive. In all these respects rheumatic aortic regurgitation differed essentially from the atheromatous, and the prognosis was very much more favorable. Not infrequently free regurgitation might exist for years with a complete absence of symptoms, even though the patient led an active life. The atheromatous cases were by far the most numerous and serious, and presented the following distinctions: (1) The disease was essentially a degeneration and arose in middle life, rarely before the age of thirty-five years, except when syphilis was the main cause; (2) the arteries were always involved to a considerable extent; (3) the heart muscle was rarely sound; (4) the disease was almost always progressive, and (5) it affected the male much more frequently than the female. Of the atheromatous cases there were four chief subdivisions, according to the mode of production: (1) The syphilitic, arising generally between the ages of thirty and fifty years, affecting sometimes mainly the aorta and branches, and sometimes mainly the valves, difficult to distinguish from fusiform aneurism, and rapidly progressive; (2) those arising from laborious work in strong, muscular men, generally between the ages of forty and fifty years; (3) the arterio-sclerotic, arising between the ages of fifty and sixty-five years in the gouty and in men who habitually ate and drank too much, especially when combined with hard mental work; and (4) cases arising from "old age," about seventy years. No general rule could be laid down for all cases as regarded the use of digitalis. It was most useful when there was consecutive mitral disease

with dropsy, next in the rheumatic cases and those arising from laborious work; the latter could often be enabled to continue their work by daily doses of digitalis. The chief cause of failure of compensation was degeneration of the ventricle from fibroid change, the prognosis of which depended mainly upon the degree of occlusion of the coronary arteries. When the fibroid change was advanced digitalis had little tonic stimulating effect upon the heart, and not only failed to do good, but did positive harm, because it still caused tonic contraction of the small arteries and increased the work of the failing heart. Digitalis was of great use in failure of compensation from temporary causes. It generally did harm in the syphilitic, the arteriosclerotic, and the aged cases.—*Lancet*, March 13, p. 741.

Diuretic Treatment of Renal Dropsy.—Dr. Nestor Tirard (*British Medical Journal*, March 20th), in a lecture on this subject, states: "It may be well to remind you that Manquat classified diuretics as follows: 1. Mechanical diuretics, with the subdivisions (*a*) cardio-vascular diuretic, (*b*) aqueous diuretics. 2. Renal diuretics, subdividing into (*a*) functional epithelial diuretics, (*b*) irritant epithelial diuretics. You will see from this classification that digitalis and diuretin, salicylate of theobromine and sodium, probably belong to different groups. Digitalis stands as a 'cardio-vascular diuretic,' which will act partly by increasing the blood pressure generally, and partly by increasing the speed of the flow of blood through the glomeruli; in fact, digitalis is to be grouped together with convallaria, squills, ergot, strophanthus, and caffeine. Of the 'aqueous diuretics' in the above classification, we made use both of Imperial drink and of milk; and these act by increasing the volume of the blood, and by thus directly raising the arterial tension. All classifications of remedies are necessarily imperfect. Some of the 'aqueous diuretics,' notably milk, might with equal propriety fall into the second group of 'renal' diuretics, which act directly on the renal epithelium. Huchard has grouped together the indications for diuretic medication, as set forth by various authors, in the following way: 1, To maintain the action of the kidney; 2, to evacuate fluid effusions; 3, to soothe and diminish irritation of the genito-urinary organs; 4, to modify the urinary excretion, to prevent urinary calculi; 5, to exert a derivative action through the renal passages; 6, to hasten elimination of toxic substances from the organism; 7, to free the blood of morbid matters which are capable of elimination by the kidneys. With cases of acute dropsy, such as occur subsequently to scarlet fever, you well know that our practice is to stimulate the action of the skin so far as possible by the employment of diaphoretics, or by using the hot-air bath or the wet pack; and while we endeavor in this way to relieve strain upon the engorged vessels of the glomeruli, we almost as a matter of routine administer hydragogue purgatives, by means of which we hope, by reducing the volume of blood within the vessels lining the intestine, to exert an absorbent action through the vessels of the remoter tissues. There are few facts in medicine which appear to be more conclusively proved than that the total quantity of fluid circulating within the blood-vessels always tends to remain the same, so that when the vessels are depleted at one part of the body the loss is replaced by absorption from other parts."

Remarks on Arthritic Gout.—Dr. Wade (*British Medical Journal*, February 27th) says: "The neurosis is the primary and essential element. If a sensory nerve is attacked, we get pain and tenderness; if a vasomotor one, we get redness and swelling; if the nutritive nerve of a joint, we get changes in the joint, one result of which may be a deposit of urates. I submit from this that this theory, more completely than any other, brings into line the various manifestations of gout. But it may be asked how it is that one toxin (uric acid) affects now an external, now an internal, sensory nerve; now a motor, now a vasomotor, now a trophic nerve, now an excretory one. This raises an important question, on which Dr. Ewart says: 'We still hesitate, then, to admit without further investigation that gout is primarily dependent upon uric acid as a cause, or that uric acid necessarily exerts any exclusive influence on the production of the phenomena of goutiness.' Dr. Ewart's hesitation is shared by many. It is enhanced in my mind by the fact that different toxins have an elective affinity for different nerve tracts. Conversely we perhaps may infer that affections of different nerve tracts imply different toxins. That such may be the case in gout receives strong support from the ingenious and laborious researches of Dr. Haig. This uncompromising advocate of the uric-acid theory claims to have proved that other bodies chemically allied to, but not identical with, uric acid resemble it in their action upon the human body. This, then, is a matter which, like the state of the local nerves, deserves a much more critical investigation than either has as yet received."

Amœboid Bodies in the Blood of Vaccinated Monkeys and Children and in that of Cases of Variola.—As the result of an experimental study, Surgeon Walter Reed, U. S. A. (*Journal of Experimental Medicine*, vol. ii., No. 5, September 18, 1897, p. 515), has been able to confirm the observation that small granular amœboid bodies are present in the blood of vaccinated children and calves, and in that from cases of variola during the stage of fever. Nuclei in any of these bodies could not be positively made out. Similar granular amœboid bodies, having a diameter about one-third that of a red blood cell, were found also in the blood of monkeys during the active stage of vaccination, disappearing with the decline of the local inflammation. A body of like appearance, granulation, and size was occasionally found in the normal blood of monkeys and children. Pale amœboid bodies containing a few dark pigment-like granules were found in the blood from cases of variola and in that of a variolated monkey. Bodies of like appearance were occasionally found in the blood of vaccinated children and monkeys.

The Spinal Lesions of Progressive Pernicious Anæmia and of the Secondary Anæmias of Adults.—Lenoble reports a fatal case of progressive pernicious anæmia, attended by hemorrhage into the spinal cord; and also one of anæmia secondary to pregnancy, in which no spinal lesion could be detected. From a study of the literature, he expresses the opinion that both forms of disease may be attended by spinal lesions varying from hemorrhage to extensive areas of sclerosis occupying a large portion of the white fibres; the gray matter also may be more or less profoundly involved up to a disappearance of various groups of ganglion cells. The lesions may, upon the one hand, be unattended by any physical evidence of their existence, or, on the other hand, they may be attended by symptoms attributable to irritation of the cord or even of true paralysis, in accordance with the extent and distribution of the lesions. These alterations appear to be especially physical, the poison of pernicious anæmia acting upon the elements from which the red blood corpuscles are derived, the hæmatoblasts. In the symptomatic anæmias, a similar mechanism may give rise to hemorrhage consecutive to the auto-intoxication that constitutes a part of the clinical syndrome.—*Revue de Médecine*, June 10, 1897.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

PUBLISHERS

WM. WOOD & CO., 43, 45, & 47 East Tenth Street.

New York, October 9, 1897.

NATIONAL QUARANTINE.

THE inefficiency of independent local quarantines in the yellow-fever districts demonstrates in a striking way the need for a national system which shall comprise all others and direct all others. The practical sanitarian need only study the present situation in all its details of senseless and conflicting restrictions, to be convinced of the fact that quarantine as at present carried on has been an utter failure. The lack of systematic direction by centralized power is strikingly shown by the inconsistent and ill-timed actions of the health boards and municipal governments of the different localities in the stricken districts. Not only has each State a health law of its own, but each city presumes to dictate by means of shotgun methods who shall enter or leave a given place, and in many instances the panic-stricken citizens have practically resorted to mob rule in holding up railroad trains, interfering with traffic, arresting government experts, hindering food supplies, and attacking temporary hospitals. It is quite true that the various State health boards specially interested in the present means of protection have done their best to establish some uniform system of quarantine and have held conferences to that end, but behind all seeming agreement on mooted points rest their obligations in maintaining the legal rights of their respective States. Therein in fact is the principal difficulty in coming to an understanding as to what may be done for several States as a consistent whole and in the common interests of wide ranges of territory.

In the various national health bills that have heretofore been framed, the intentions have been very clearly expressed not to interfere with the rights of any State in the codification or enforcement of its own laws. The leading ideas were uniformity in quarantine regulations, and such assistance from a centralized power as might be necessary in times of great emergency to enforce consistent and concerted action among different States.

Some attempt at nationa. control has been made during the past few years by enlarging the powers of the Marine Hospital department, but, while due credit is to be accorded to the Supervising Surgeon-General and his alert staff, it has become more and more evident that something more is needed to give due scope and efficiency to a model, far-reaching, and thoroughly practical national law. We must needs have some such enactment ere long. Every time we have a practical object lesson in the shape of an epidemic the real necessity for such a measure becomes more and more manifest. Just now the subject forces itself on our attention, and we duly note current facts as contributing to the history of a discussion in which every sanitarian in the country should be duly interested.

MODERN ATHLETICS AND HEALTH.

ARE athletics as now carried on conducive to health? is a question often asked, and some curiosity is evinced as to what point of barbarity they will attain ere public sentiment revolts against their methods. There is an ever-growing tendency among sensible and thoughtful men to deplore the manner in which our modern sports and games are conducted. The spirit of emulation is an excellent quality, but even that may be carried too far; and when, as not infrequently happens, limbs are broken and fatal casualties occur in what are supposed to be friendly football games between boys at school or university, it is time that the situation should be reviewed dispassionately. As with the mode of playing football, so it is with the methods ruling the conduct of modern athletics generally. The system is not only not beneficial but is prejudicial to health. In the journals of England a heated discussion is now being waged with regard to this much-vexed question. Letters are being written and opinions aired by all sorts and conditions of men, and from these it would appear that the conclusions arrived at are unfavorable to the view of the healthfulness of modern athletic training. The *British Medical Journal* has taken up the subject, and says: "We quite admit that many athletes are extraordinarily healthy fellows, but that does not touch the question. None but strong and healthy men are likely to enter on or at any rate to persevere in athletic pursuits, and the question really is not, Do some of them remain healthy? but, Do they remain as healthy when they devote themselves to the one object of developing muscle as they, the same people, would if they led an ordinary outdoor life, eating ordinary food and taking a reasonable amount of exercise without any attempt at interfering with their weight or increasing their muscles? The key to the answer lies in the fact that health depends on the integrity of the digestive and assimilative organs, and that perfection of muscle is quite a secondary consideration. . . . Notwithstanding, then, the array of vigorous and hearty middle-aged and even elderly men who have survived the ordeal, we cannot shut our eyes to the fact that the record breaking which is now the aim of every self-respecting athlete is productive of such an amount of strain, especially to the vascular system, as when oft repeated must do harm. The athlete is often healthy, but is so in spite of rather than by virtue of his athleticism."

These are true words, and apply probably even more directly to American athletes and to the American system of training than to athletes of England who follow

the system in vogue there. The course of training at universities in this country is much more severe than in England. However, there is small room for doubt that in both countries athletics, and more particularly among amateurs, is carried to excess. Of course if a man is a professional and gains his livelihood by the exercise of his thews and sinews, he must expect to run some risks, but with those who hope in after-life to work at a profession or trade it is foolish in the extreme to mortgage their future by injuring their health when at school or college. Moderation is good, excess is bad.

HIRED EXPERT TESTIMONY.

The sensational trial of Luetgert throws its glary sidelights on the anatomical experts who are disputing over the identity of the bones found in the sausage vat. The public is being amused by the flat contradictions of alleged scientists regarding certain points which distinguish the bones of a woman from those of a hog. What a credit to anatomy such a lamentable possibility of radical disagreement entails! It is such spectacles in court that show the utter fallacy of hired expert testimony. How much better would it be for the court to appoint an impartial commission of skilled anatomists, which could decide once for all without the disgraceful wrangle and without the temptation for disagreement which the mere payment of a nominal fee would appear to invite!

"THE URIC-ACID DIATHESIS."

Dr. Haig has imparted a good deal of breezy freshness into the dry "uric-acid diathesis" question, and his theory as to the cause of uric acid in the body is worthy of much consideration. Nevertheless it can hardly be said that his researches, valuable and interesting as they are, have finally settled the point in dispute. In fact, those holding his ideas on the subject are in the minority. In the *Edinburgh Medical Journal* for July is printed a paper which Dr. Haig read before the Medical Society of London in November last, and in which his views are clearly and concisely set forth. He begins by saying: "It has been taught for many years that uric acid given to mammals appears in the urine as urea. If this is so, then it is impossible to increase the uric acid in a man's body and blood by administering it in his food. Thus almost the only way in which a man can come to have excess of this substance in his body and blood is by excessive formation. That some have such excessive formation and suffer from excessive uric acid as the result of it, is the belief of those who write about the 'uric-acid diathesis.'" Dr. Haig then states that as the result of investigations he found that uric acid did get into the blood and eventually into the urine, and that from further investigations he has completely convinced himself that to speak of "a uric-acid diathesis" is altogether misleading. He thinks the excess of uric acid in the body and all the diseases to which it gives rise can be quite as well accounted for by the gradual accumulation of the quantities daily swallowed in the food. When a diet in every respect free from all uric acid has been tried, and when the urine of the individual who has thus been dieted has been found quite free from uric acid, then Dr. Haig's assumption undoubtedly will be accepted; but as yet the theory needs support.

News of the Week.

Dr. H. Davison Schwarschild announces that he has assumed the name of Dr. H. Davison Saril, by virtue of an order of the supreme court.

Prof. Adami, of McGill University, Montreal, has accepted the invitation of the University Medical College to deliver a course of lectures on general pathology. The course began on Friday, October 8th.

St. Mark's Hospital Alumni Association. — The graduates of St. Mark's Hospital have formed an alumni association. Meetings will be held monthly at the hospital. The officers are Dr. L. F. Garrigues, *President;* Dr. Martin J. Schuh, *Secretary;* Dr. Casper Stock, *Treasurer.*

The American Laryngological, Rhinological, and Otological Society.—The fourth annual meeting of this society will be held in Pittsburg, Pa., on May 11 and 12, 1898. The president is Dr. William H. Daly, of Pittsburg, Pa.; and the secretary, Dr. Robert C. Myles, 46 West Thirty-eighth Street, New York City.

A State Medical Examination in England.—Mr. Victor Horsley is a candidate for the vacancy in the General Medical Council. At a recent meeting of medical men he delivered an address, in which he declared in favor of what he called the one portal system—that is, a single State examination instead of the dozen or more conducted by various corporations and schools, on which the authorities at present are empowered to grant medical diplomas.

Opposition to the Establishment of a Sanatorium.—The New York State board of health recently asked the attorney-general to give an opinion as to whether a local board of health has the right to prevent the establishment within its jurisdiction of a sanatorium for the treatment of pulmonary tuberculosis. A physician of this city had made application to the village authorities of Liberty, in Sullivan County, for permission to establish one. The application was refused on the ground that its existence would be a menace to the general health of the village. He appealed to the State board of health for the annulment of the decision of the local board. In response to this request, Attorney-General Hancock has written an opinion, in which he says that "the members of the State board of health are sufficiently familiar with the disease called tuberculosis to advise whether such a resolution as has been adopted is reasonable or proper. In my opinion the mere fact that this disease is com-

municable under certain circumstances would not justify an ordinance or regulation preventing the establishment of a properly regulated sanatorium within the corporate limits of the village."

A Modern Epidemic of Mediæval Type.—A striking proof that the great plagues of antiquity and the middle ages are kept away only by modern sanitary measures is furnished by the epidemic of typhoid fever now raging at Maidstone in England. In this town of thirty-two thousand souls there are more than thirteen hundred cases of typhoid fever, the greater proportion of them among the well-to-do. The streets are nearly deserted, the shops are closed, the church bells are silent. The origin of the epidemic is most evident, and the presence of the disease is a disgrace to the sanitary authorities. Ninety-six per cent. of all the cases have been traced to one water supply, which receives the drainage from a field where there was an encampment of hop pickers. The first cases of the fever occurred just two weeks after the hop pickers arrived from London. These people were huddled together like sheep and lived under frightfully insanitary conditions, more like swine than human beings. The attention of the authorities has been called to this state of affairs in previous years during the hop-picking season, but they did nothing to avert the danger.

The Surgeon-General of the Navy.—The President has appointed Dr. Newton C. Bates surgeon-general and chief of the bureau of medicine and surgery of the navy, to succeed Surgeon-General Tryon. Dr. Bates is an old friend of Mr. McKinley, and has been his family physician since the inauguration.

American Medical Association of Colored Physicians.—The second biennial session of the American Medical Association of Colored Physicians will be held at Nashville, Tenn., October 15th and 16th. A number of papers has been promised by the leading colored physicians of the North and South.

Obituary Notes.—Dr. James T. Sothoran, of Washington, died in that city on September 27th, aged fifty-five. He was a native of Maryland, but had resided in the District of Columbia since early youth. During the civil war he served as a medical cadet in one of the army hospitals at Washington. He was a graduate of the medical department of the University of Georgetown in 1865.—Dr. William P. Jones, of Nashville, died in that city on September 25th, aged seventy-eight years. He was a native of Adair County, Ky., and had been a resident of Tennessee for nearly fifty years. Dr. Jones had been postmaster of Nashville and president of the Nashville Medical College. He was a graduate of the Medical College of Ohio in 1854.—Dr. Samuel J. Craig, who was attached to the Ward's Island Hospital, died September 30th, at the home of his father in Williamsburg, of typhoid fever. He was twenty-six years old, and graduated three years ago from the College of Physicians and Surgeons in this city.—Dr. Charles T. Ryan, of this city, died on October 1st, aged fifty years. He was a graduate of Bellevue Medical College, but never practised medicine.—Dr. Robert N. Flagg, of Yonkers, died in this city on September 30th, from injuries received by jumping out of a window while insane. He had been ill for some time, but was thought to be better, and had been married only a short time before his death.—Dr. Joseph J. Sweet, Jr., of Albany, died in the City Hospital there on October 3d. He was born in New Hampshire in 1865, and was graduated from the Albany Medical College in 1894.

The Health of New York State.—According to the bulletin of the State board of health for August, the total number of deaths during the month was 10,084, which is 2,300 less than in August, 1896, and is almost 500 less than the average for August for the last ten years. Last year there were 1,125 deaths from sunstroke during the month of August, but very few during the same month this year. In the cities of New York and Brooklyn there were 1,750 fewer deaths than in the corresponding month last year. The death rate for the month was 18.75, against 23.25 last year.

Hotel Suicides.—On the last day of September there were seven attempts at suicide in different hotels in this city, all of which were successful. Six persons found death by inhalation of illuminating gas, and one died by jumping from a window.

The Plague in Bombay is rapidly assuming its former proportions. During the last week of September there were sixty deaths from that disease in the city of Bombay, and many more in the presidency. The plague has reappeared in Kurrachee and is spreading to other towns, having already invaded Sholapur.

Dr. A. E. Sansom, president of the Medical Society of London, well known to Americans through his writings on diseases of the circulatory system, has been elected an honorary member of the Therapeutical Society of Moscow.

Dr. Eng, a Chinese lady, said to be a graduate of the Women's Medical College in Philadelphia, has been appointed physician to the women of the household of Li Hung Chang. She has also been appointed, with Miss Wang, a delegate from China to the Women's Congress which is to be held in London in 1898.

Dr. William L. Rodman, of Louisville, has been called to the chair of the principles and practice of surgery and clinical surgery in the Medico-Chirurgical College of Philadelphia. He will deliver a course of lectures, didactic and clinical, between October 1, 1897, and January 1, 1898, and will then resume his work in the Kentucky School of Medicine, where he has held the chair of surgery for several years.

Professor Virchow and the Lady Doctors.—After the scientific proceedings of the International Medical Congress at Moscow had been brought to a close, a deputation of Russian lady doctors waited on Prof. Rudolf Virchow, who received them in the apartments assigned to him by the Czar in the Kremlin. The

spokeswoman of the deputation thanked the great pathologist in the name of her professional sisters for his championship of the cause of the medical education of women. Professor Virchow, in returning thanks, spoke highly of the ability shown by Russian female students of medicine, and expressed the opinion that the Medical Institute for Women, recently opened in St. Petersburg, had a future of usefulness before it. He invited the Russian lady doctors to make free use of his Anatomico-Pathological Institute if they ever had occasion to visit Berlin.—*British Medical Journal.*

Dispensary Abuse in Philadelphia.—The managers of the Presbyterian Hospital in Philadelphia, in conjunction with the medical staff, have instituted an inquiry into the extent of the abuse of its privileges by those who are able to pay. The result of a careful investigation shows that about twenty per cent. of those who are treated freely in the out-patient department are not proper subjects for charity; about half of these are willing to pay moderate fees, but apply because their friends are treated gratuitously and successfully; they have no family physician. They have no incentive to seek medical attention outside when it is so easy to get advice free of charge in institutions. A plan of personal visitation will be adopted, by which an effort will be made to give services only to those who are really unable to pay for medical attendance; thus the needy poor will receive more satisfactory treatment and the objects for which the founders and contributors of such an institution maintain it will be conserved. Co-operation by other hospitals will help to remedy a great evil.—*International Medical Magazine.*

Dr. Alarik Frithiof Holmgren, professor of physiology at the University of Upsala, died recently at the age of sixty-five years. He graduated in medicine in 1861, and was called to the chair of physiology by his alma mater in 1864. He was best known abroad perhaps by his labors in relation to color blindness, and the worsted test for color perception is known as Holmgren's test. He was founder and editor of the *Skandinavian Archives of Physiology*, and was president of the International Physiological Congress.

A Well-Equipped Medical School.—Among the million or more medical colleges in this great country there is one with thirty-eight professors, twenty-three assistant professors and instructors, and fifty-one students. This gives one professor, assistant professor, or instructor to each student, with ten left over. It is suggested that a new medical journal be started, to give the idle ten something to do.

War by Anæsthesia.—A Russian chemist is reported by the *British and Colonial Druggist* to have discovered a substance with most powerful anæsthetic properties, which exerts its influence over a wide area even when greatly diluted with air. It is proposed to determine whether it will not be possible to inclose the anæsthetic in bombs, which could be thrown into an enemy's ranks and there exploded, thus anæsthetizing large bodies of troops and rendering them an easy prey. This would give a new application to the phrase, "putting one's adversary to sleep."

A Quarrel of Kneipp's Successors.—Dr. Baumgarten and Father Reile are engaged in a sharp struggle to determine which shall be the successor of the late Father Kneipp in the management of the water-cure establishments at Woerishofen. The newspapers, inhabitants, and patients are taking sides in the quarrel, and a manifesto signed by two hundred patients has just been published against Father Reile and in support of Baumgarten.

A Suit against Montreal.—A bicyclist, while riding his wheel on one of the public streets of Montreal, fell and was severely injured. He attributes his fall to the bad condition of the roads, and thinks the city can be made by law to keep good roads, since it forces all wheelmen to pay a tax for the privilege of riding on them. He sues for $5,000 damages.

Ferràn's Anti-Cholera Injections.—Dr. Ferrán, of Barcelona, recently sent a communication to the Paris Academy of Medicine, in which he seeks to establish his claim of priority in the treatment of cholera by anticholeraic injections, as practised by him in Spain in 1885. It was objected, however, that the results of these injections were not always as favorable as Ferrán claimed; indeed, the treatment was said to have been so injurious that it was formally forbidden by the Spanish government. Furthermore, Ferrán refused in 1885 to give up the formula of the composition of his vaccine, and still persists in this refusal. Under these conditions the academy has declared that it can neither give any decision as to the curative virtues of a preparation of which it knows nothing, nor give any support to Dr. Ferrán in his claim for priority.

A Leper Hospital in Iceland.—The Odd Fellows in Denmark have recently raised by subscription about $30,000 to build a hospital for lepers in Iceland. The city of Reykjavik has presented for the site the peninsula Langarnaes, which is about two miles out of town, and all running-expenses are to be borne by the government of Iceland. A law has recently been passed by the Althing empowering the health authorities in the island to compel the isolation of patients wherever such a precautionary measure seems to be necessary. The erection of the hospital is the direct outcome of an investigation by Dr. Edward Ehlers of leprosy in Iceland, which showed that the disease is steadily on the increase while little has been done hitherto to prevent its spread.

End of the Small-pox in Montreal.—The health authorities of Montreal have declared that the small epidemic of small-pox, from which the city has suffered for some time, is now over, there having been no cases there for upward of three weeks.

Trichinous Pork in Germany.—A man in Cologne was recently detected selling trichinous pork, and when brought up for trial said the hams and sides of bacon were of American origin and in their original packages, but the evidence at the trial disproved this. All the trichinous hams, fourteen hundred and ninety altogether, had been imported from Servia.

Reviews and Notices.

THE AMERICAN TEXT-BOOK OF OPERATIVE DENTISTRY. In contributions by eminent American Authorities. Edited by EDWARD C. KIRK, D.D.S., Professor of Clinical Dentistry, University of Pennsylvania, Department of Dentistry. Philadelphia: Lea Brothers & Co 1897.

ONE whose knowledge of dentistry was obtained only a few years ago but who has not kept thoroughly in touch with the rapid advances in this branch of medical science would be astonished on opening this work to see what has been accomplished in the past decade; almost a new science has been created. Dentistry is sometimes regarded as a special branch of surgery, but in reality it is a profession in itself, divided into almost as many specialties as is the profession of medicine. Because of this high specialization the preparation of this work has been intrusted to many hands, the writers, in addition to the editor Dr. Kirk, being Drs. R. R. Andrews, H. H. Burchard, C. S. Case, W. E. Christensen, D. M. Clapp, M. H. Cryer E. T. Darby, C. L. Goddard, L. H. Guilford, Louis Jack, L. Ottofy, C. N. Pierce, J. D. Thomas, and A. H. Thompson.

The work is divided into three parts, dealing respectively with (1) dental anatomy, histology, and embryology; (2) operative dentistry; and (3) dental orthopædics, including orthodontia and the modification of facial contours. The subject of prosthetic dentistry, including crown and bridge work, is touched upon only incidentally, the reader being referred to a companion volume for the discussion of this interesting subject. The volume, while intended primarily, of course, for the use of practising dentists, will be found of great interest and utility to physicians as well, not only because an intelligent conception of this cognate science is an accomplishment, but also because physicians are often called upon to do more or less dental work, and in any event should be able to recognize the nature of buccal disorders and to decide which belong properly within the domain of the dental surgeon. The book is profusely illustrated, handsomely printed, and well bound.

ENCYKLOPAEDIE DER THERAPIE. Herausgegeben von OSCAR LIEBREICH, Dr. Med., Geheimer Medicinalrath, o.ö. Professor der Heilmittellehre an der Friedrich-Wilhelms-Universitat, unter Mitwirkung von MARTIN MENDELSOHN, Dr. Med., Privatdocent der inneren Medicin an der Friedrich-Wilhelms-Universität, und ARTHUR WÜRZBURG, Dr. Med., Kgl. Sanitätsrath, Bibliothekar im Kaiserlichen Gesundheitsamte. Zweiter Band, II. Abtheilung, I. Lieferung. Berlin: August Hirschwald 1897.

THIS first section of the second part of the second volume of this excellent cyclopedia of therapeutics carries the work as far as Gly. Among the more important titles are flatulence, foreign bodies, furuncle, bile, gall-bladder, galvanocautery, gangrene, gastritis, secret remedies, brain, apoplexy, brain surgery, cerebral meninges, mental diseases, articular rheumatism, gout, facial atrophy, œdema of the glottis, glycerin, licorice, and glossitis. The high standard of this valuable work is fully maintained in the present fasciculus.

A HANDBOOK OF MEDICAL CLIMATOLOGY. Embodying its Principles and Therapeutic Application, with Scientific Data of the Chief Health Resorts of the World. By S. EDWIN SOLLY, M.D., M.R.C.S., late President of the American Climatological Association. Illustrated in black and colors. Philadelphia: Lea Brothers & Co. 1897.

THIS is an attempt, and a fairly successful one, to meet the want, which has long been felt, of an authoritative work on climatotherapy. The work is divided into three parts, the first dealing broadly with climatology in general and medical climatotherapy in particular; the second treating of climatotheraphy, strictly speaking; and the third describing special climates and individual health resorts. All parts of the world are considered, and the principal resorts of Europe in especial are described as regards the indications which they offer in the management of individuals, yet naturally the resorts in the United States receive particular attention and are described at greatest length. The author, as might be expected, betrays an enthusiastic admiration of the climate of Colorado, which is not shared by all who have experienced its rigors. Yet his praise is innocent enough, and the reader can temper it sufficiently by noting the temperature statistics. The book is provided with a number of charts showing elevation, rainfall for different seasons, etc. We can safely recommend Dr. Solly's work to all who need a book of reference on climatotherapy, and this means all practising physicians.

THE POCKET THERAPIST. A Concise Manual of Modern Treatment for Students and Junior Practitioners. (Arranged alphabetically for ready reference.) By THOS. STRETCH DOWSE, M.D., F.R.C.P. Ed. Bristol: John Wright & Co. 1897.

THIS is a useful little work which contains many a hint as to treatment that may serve one in good stead when worried by an obstinate case. The author has not jumbled together a mass of prescriptions for every imaginable malady, but suggests usually one line of treatment for each disease, recommending in many cases that which he has found by practical experience to be of greatest value.

THE DISEASES OF WOMEN. A Handbook for Students and Practitioners. By J. BLAND SUTTON, F.R.C.S. Eng., Surgeon to the Chelsea Hospital for Women, Assistant Surgeon, Middlesex Hospital, London; and ARTHUR E. GILES, M.D., B.Sc., F.R.C.S. Edin., Assistant Surgeon, Chelsea Hospital for Women, London. With 115 illustrations. Philadelphia: W. B. Saunders. 1897.

THIS is a handy volume of small size. The entire subject of gynæcology is satisfactorily covered in the four hundred and thirty pages, though necessarily the different topics are treated with considerable brevity and conciseness of language. The binding is poorly done, many of the pages having become loose during the reading of the book by the reviewer.

THE OPHTHALMOSCOPE. A Manual for Students. By GUSTAVUS HARTRIDGE, F.R.C.S., Surgeon to the Royal Westminster Ophthalmic Hospital, Ophthalmic Surgeon to St. Bartholomew's Hospital, Chatham, etc. Third Edition. Philadelphia: P. Blakiston, Son & Co. 1897.

THESE instructions in the use of the ophthalmoscope are exceedingly clear and understandable, and any one who might find it necessary to learn how to use this really indispensable instrument, and had not the advantage of a teacher, could almost certainly teach himself by means of this book. The comprehension of the text is greatly facilitated by the illustrations, of which there are over seventy, some of them colored.

NOTES ON PATHOLOGY. For Students' Use. By W. A. EVANS, B.Sc., M.D., Professor of Pathology in the Medical School in the University of Illinois, Professor of Pathology in the Milwaukee Medical College, Pathologist to the Columbus Medical Laboratory, etc. Chicago: The W. T. Keener Company. 1897.

THESE "notes" are well and systematically arranged; probably after the order of the author's lectures, and so will serve admirably for the use of those who have the privilege of sitting under his instruction. But other students may profit by them as well, and can take their own notes when the lecturer expresses his facts in another way. To facilitate this extra note taking, the book is so printed that every other page is blank. The book is of a handy size to be carried to the lecture room.

A TEXT-BOOK OF DISEASES OF WOMEN. By CHARLES B. PENROSE, M.D., Ph.D., Professor of Gynæcology in the University of Pennsylvania, Surgeon to the Gynecean Hospital, Philadelphia. Illustrated. Philadelphia: W. B. Saunders. 1897.

THE appearance of a new work on gynæcology at this time does not strike us as in response to an urgent demand from a profession thirsting for knowledge on an obscure subject. This book, however, possesses the advantage of having been written professedly for the student, and may possibly therefore be of service to the practitioner who grudges the time wasted in reading details of anatomy and physiology. Dr.

Penrose refers his readers to the ordinary anatomical text-books if they lack the necessary familiarity with these elements. In discussing treatment, the author recommends usually but one method for each individual disease, thereby avoiding creating confusion in the mind of the student or young practitioner who turns to the work for instruction. The illustrations are fairly artistic and are for the most part helpful.

CONVERGENT STRABISMUS AND ITS TREATMENT. By EDWIN HOLTHOUSE, M.A., F.R.C.S., Surgeon to the Western Ophthalmic Hospital. Philadelphia: P. Blakiston, Son & Co. 1897.

THIS is an essay based upon a careful study of the cases of squint coming under treatment during a period of about two years in one of the classes at the Royal London Ophthalmic Hospital. The author shows quite conclusively that strabismus is not such a threshed-out subject as it is generally supposed to be, for he advances much that is novel in this study, and makes suggestions that may well serve as a basis for other and further investigations in this interesting field.

CRIME AND CRIMINALS. By J. SANDERSON CHRISTISON, M.D., formerly of the New York City Asylums for the Insane, Blackwell's Island and Ward's Island, etc. Chicago: The W. T. Keener Company. 1897.

DR. CHRISTISON may well pray to be saved from his friends, for he states in his preface that it was they who urged him to publish in book form a series of articles contributed to the Chicago *Tribune*. Separately the sketches of types of criminals might have served to amuse the readers of a Sunday edition, but collectively they lack unity, weight, and all the qualities necessary to make a useful treatise on criminal anthropology or any other subject.

DIE GESCHICHTLICHE ENTWICKELUNG DER SOGENANNTEN HIPPOKRATISCHEN MEDICIN IM LICHTE DER NEUESTEN FORSCHUNG. Eine geschichtlich-medicinische Studie. Von DR. MED. FRANZ SPAET. Berlin: S. Karger. 1897.

THIS is an interesting study, by a man who knows his subject, of the teachings of Hippocrates and, incidentally, of their influence upon the development of scientific medicine of the present day. The brochure is a valuable addition to the literature of historical medicine.

THE EDINBURGH MEDICAL JOURNAL. Edited by G. A. GIBSON, M.D., F.R.C.P. Ed. New Series, Vol. I. Edinburgh and London: Young J. Pentland. 1897.

THIS bound volume of the first of the new series of this old established journal is one which the new editor may well regard with pride. It is filled with articles of permanent value, written by well-known authorities, and is profusely and excellently illustrated.

DIFFERENTIAL DIAGNOSIS AND TREATMENT OF COMA. Embracing Points in the Lectures of, and Revised by, A. P. GRINNELL, M.D., Medical Department, University of Vermont. Arranged by GEORGE A. HUNTLEY, M.D., Burlington, Vt.

THIS is a well-arranged table of the chief points in the differential diagnosis of the various forms of coma. Ambulance surgeons and police surgeons, the former especially, might avoid many serious and humiliating blunders if they would make themselves thoroughly familiar with the symptoms of the different states of unconsciousness as arranged in this chart.

DISEASES OF THE LIVER, GALL BLADDER, AND BILIARY SYSTEM. Their Pathology, Diagnosis, and Surgical Treatment. By H. J. WARING, M.S., B.Sc. Lond., F.R.C.S. New York: The Macmillan Company. 1897.

AFTER a concise description of the anatomy and physiology of the liver, the author describes in an exhaustive and thorough way all the diseases of this organ and its attachments. Waring does not recognize a "hæmatogenic" jaundice, and is herein in harmony with most recent writers; for it has been conclusively proved that if the liver be extirpated, or rendered functionless by isolation, no accumulation of biliary constituents results. The section on symptomatology and diagnosis of "abscess of the liver" is one of especial merit by reason of the clearness by which the author depicts the characteristic signs by which the existence of this condition can be recognized. The operative treatment in affections of the liver and gall bladder is given full weight and is minutely described. As a whole the book can be highly recommended and the reader will greatly profit by its perusal.

BULLETIN OF THE HARVARD MEDICAL ALUMNI ASSOCIATION. No. 10. Catalogue. Boston. 1897.

THIS number is given up almost wholly to the local lists of members, etc., including an alphabetical list of members

ILLUSTRATED SKIN DISEASES. An Atlas and Text-Book, with Special Reference to Modern Diagnosis and the Most Approved Methods of Treatment. By WILLIAM S. GOTTHEIL, M.D., Professor of Skin and Venereal Diseases at the New York School of Clinical Medicine, etc. New York: E. B. Treat & Co. 1897. Portfolios 7, 8, and 9.

THE uncolored pictures of this atlas are the best, and in saying this we would not convey the impression that they are above the average. Indeed, unless the label were attached, difficulty would at times be found in telling whether an eruption were papular or pustular, and the old lady with furunculosis of the face might as well have been said to have one of a half-dozen affections. The tints of the lesions, of the surrounding healthy skin, of the hairy portion, and of the background do not show sufficient contrast, and it is difficult to tell in some of the lithographs whether the blueness of the skin is a pathologic or an artistic effect. There have been so many skin atlases produced of late that one scarcely sees what field can be filled by works other than those of exceptional merit of production. The text is good.

EXCRETORY IRRITATION AND THE ACTION OF CERTAIN INTERNAL REMEDIES ON THE SKIN. By DAVID WALSH, M.D. Ed., Physician to the Western Skin Hospital, London, W. London: Baillière, Tindall & Cox. 1897.

THIS is a little work of sixty odd pages, neatly bound in red, comprising an inaugural thesis and a paper read at the London Congress of Dermatology. The theory is maintained that certain eruptions are due to direct irritation of excretory glands in the skin, and that if the theory is correct their internal disorders must often depend upon a like cause. On page 61, where Dr. Duhring of New York is referred to, the author probably means Dr. Duhring of Philadelphia.

OM ENDOKARDITI, DENS PATHOLOGISKE ANATOMI OG ÆTIOLOGI. Af FRANCIS HARBITZ, 1ste Assistant ved Rigshospitalets Pathologisk-Anatomiske Institut. Kristiania: Steenske Bogtrykkeri. 1897.

THIS work contains the results of the author's studies during a period of three years in the Pathological Institute in the public hospital at Christiania. He divides the cases into two classes, according as the endocarditis is manifestly of infectious origin or as a careful study fails to demonstrate any such pathogenesis. The book is a valuable addition to the world's literature of this interesting subject.

LE TRAITEMENT DU MAL DE POTT. Par le DR. A. CHIPAULT. Paris: Masson et Cie. 1897.

THE author of this brochure has recently revived the ancient method of forcibly straightening out the kyphotic spine in Pott's disease, and here describes it, as well as his method of apophyseal ligatures. The book is one which orthopædic surgeons will read with interest, as it is, we believe, the first presentation in connected and systematic form of the therapeutic measures so ably advocated by Dr. Chipault.

FORMULAIRE DES MÉDICAMENTS NOUVEAUX POUR 1897. Par H. BOCQUILLON-LIMOUSIN, Pharmacien de Première Classe, Lauréat, Medaille d'Or de l'École de Pharmacie, Membre des Sociétés de Pharmacie et de Therapeutique. Avec une Introduction par HENRI HUCHARD, Membre de l'Académie de Médecine, Médecin de l'Hôpital Necker. Paris. Librairie J.-B. Baillière et Fils. 1897.

THIS 1897 edition of the "Formulary" is an improvement in some respects over the last. In others it is not. Almost

everything new in the way of methods, modes of administration of remedies, was given in the former volume. New remedies, good and bad, have been especially considered in the present work. So many drugs still in their experimental stage find a place here that it is only those who have much time to devote to their study who will care to read the book through.

PERIODISCHE DEPRESSIONSZUSTÄNDE UND IHRE PATHOGENESIS. Von PROF. C. LANGE in Kopenhagen. Deutsch von Dr. HANS KURELLA. Hamburg: Leopold Voss. 1896.

THIS little work treats of the blues in a scientific way, and elevates the condition to the dignity of an actual disease. The author shows that periodical mental depression, while resembling in some respects a mild form of melancholia, is yet far removed and easily differentiable from it. The cause he finds to reside in the action of uric acid upon the nervous centres, and deduces from this pathogenesis a rational therapy.

SOME ASPECTS OF INFANTILE SYPHILIS, BEING THE HUNTERIAN LECTURES DELIVERED AT THE ROYAL COLLEGE OF SURGEONS IN 1896. By J. A. COUTTS, M.B. Cantab., M.R.C.P., formerly Professor at the College, Physician to the East London Hospital for Children. London: Rivington, Percival & Co. 1897.

A LITTLE book of one hundred and thirty pages, just large enough to take in the pocket for an hour's journey. The text is large and pleasing to the eye, and the subject matter is pleasantly put.

THE RETROSPECT OF PRACTICAL MEDICINE AND SURGERY. Being a Half-Yearly Journal, Edited by JAMES BRAITHWAITE, M.D. Lond., Obstetric Physician and Surgeon to the Leeds General Infirmary; Assisted by E. F. TREVELYAN, M.D. Lond., B.Sc., M.R.C.P. Volume CXIV. New York: G. P. Putnam's Sons. January, 1897.

THE "Retrospect" maintains its general average of excellence, and covers in a brief way the literature of the half-year in an essentially practical manner. The index, covering several volumes, gives facility for looking up quickly any given subject.

AUTOSCOPY OF THE LARYNX AND THE TRACHEA. Direct Examination without Mirror. By ALFRED KIRSTEIN, M.D., Berlin. Authorized Translation (Altered, Enlarged, and Revised by the Author) by MAX THORNER, A.M., M.D., Cincinnati, Ohio, Professor of Clinical Laryngology and Otology, Cincinnati College of Medicine and Surgery. Philadelphia: The F. A. Davis Company. 1897.

THE aim of this little work is to show how the air passages can be directly examined and treatment applied without the use of complicated instruments. It is the author's aim to add to prevailing methods rather than to supplant them.

The illustrations add much to the ready understanding of the methods of direct inspection of the larynx and trachea by pressure upon the tongue. The translation has been well done.

A PICTORIAL ATLAS OF SKIN DISEASES AND SYPHILITIC AFFECTIONS. From the Museum of the St. Louis Hospital, Paris. Edited by J. J. PRINGLE, M.B., F.R.C.P. Parts VIII. and IX. London. The Rebman Publishing Company, Ltd.; Philadelphia: W. B. Saunders. 1897.

THE illustrations in these two numbers are in the same class as those which have previously appeared. That of pustular scabies is very true to life, while the several pictures of chilblain lupus give a good idea of this rather unusual condition. The woodcut pictures accompanying Jacquet's article on epithelioma arising from lupus tissue, as well as the colored plate, show what fearful ravages this malignant disease can make in the region of the face. There is a very fair picture of lichen planus, but not of a strictly typical case.

Comparatively, we cannot see wherein this work possesses advantage over the large and very complete atlases of Morrow and of Taylor, so recently published in this country. It would almost seem as if medical-book publishers were, some of them, overreaching themselves in crowding upon the profession such a multiplicity of books upon the same subject. This, however, is their affair, and our part is only to advise our subscribers that it is well to exercise caution in buying books, however good, when they may have already in their libraries others which are not excelled.

MEDICAL AND SURGICAL REPORT OF THE PRESBYTERIAN HOSPITAL IN THE CITY OF NEW YORK. Volume II. January, 1897. Edited by ANDREW J. MCCOSH, M.D., and WALTER B. JAMES, M.D. New York: Trow Directory Printing Company.

BESIDES the usual number of interesting reports of cases and operations, the present volume is well illustrated with views of the hospital operating-rooms, etc., from photographs by Dr. Stevens. A well-illustrated article on renal tuberculosis, by F. Tilden Brown, deserves mention. Drs. McCosh and James are to be congratulated on the appearance of the second volume.

INTERNATIONAL CLINICS: A Quarterly of Clinical Lectures on Medicine, Neurology, Surgery, Gynæcology, Obstetrics, Ophthalmology, Laryngology, Pharyngology, Rhinology, Otology, and Dermatology, and Specially Prepared Articles on Treatment. By Professors and Lecturers in the Leading Medical Colleges of the United States, Germany, Austria, France, Great Britain, and Canada. Edited by JUDSON DALAND, M.D., University of Pennsylvania, Philadelphia; Instructor in Clinical Medicine and Lecturer on Physical Diagnosis in the University of Pennsylvania, Assistant Physician to the Hospital of the University of Pennsylvania; J. MITCHELL BRUCE, M.D., F.R.C.P., London, England. Physician to and Lecturer on the Principles and Practice of Medicine in the Charing Cross Hospital; DAVID W. FINLAY, M.D., F.R.C.P., London, England; Professor of Practice of Medicine in the University of Aberdeen, Physician to and Lecturer on Clinical Medicine in the Aberdeen Royal Infirmary. Volume I. Seventh Series. Philadelphia; J. B. Lippincott Company. 1897.

THIS very praiseworthy publication comes with fresh welcome to the library table. The lectures are, as usual, of a bright and instructive nature, and all show evidence of care in preparation. Dr. Daland, the able editor, selects his contributors with much judgment, and the list comprises well-known names.

There are in the present volume forty-three articles, covering the various branches of medicine, and written mostly by specialists in the particular subject discussed. England, France, Germany, the United States, and often other countries are represented. The illustrations are well made, and the volume, as a whole, is produced with careful attention to detail.

Habitual Constipation.—The causes of habitual constipation are: Heredity; the habit of suppressing the desire; unsuitable diet—too abundant, deficient in water, too easily absorbed, or insufficient in variety; sedentary habits (although obstinate habitual constipation may occur even in those who lead an active life); disturbances in the circulation (heart disease, mechanical pressure, pregnancy); displacement of the bowel; intestinal adhesions. The treatment is given as follows: (1) dietetic, (2) physico-mechanical, (3) medicinal. In the first method such foods should be given as are known to increase peristalsis. The "physico-mechanical" includes suitable massage (often of great value), electricity, and enemata. The disadvantage of enemata is that ultimately small quantities of fluid do not suffice, and large quantities overdistend the intestine and become useless. Regular attempts at defecation with slight pressure are recommended. Medicinal treatment is discussed under two groups, mild and more powerful purgatives. An efficient rhubarb preparation is very useful. Calomel is very useful in children. Castor oil is unsuitable for constant use. Large injections of olive oil are of value. *Berlin. Klinik.*

Clinical Department.

REPORT OF A CASE OF FRACTURE AT THE BASE OF THE SKULL, WITH A PECULIAR HISTORY.

By L. W. ATLEE, M.D., U.S.N.

H. G——, white, native of England, aged seventy years, at present a pensioner of the United States; former occupation, sailor. He was brought to this hospital on December 2, 1896, at 3:45 P.M., in the police-patrol wagon, with a history of having been picked up bleeding profusely from the left ear. On admission he showed evidences of alcoholism; bleeding had stopped. He was placed in bed and bromide of potassium was administered, other treatment being expectant.

December 3d, examination revealed contusion of the lateral occipital and mastoid region on the left side. The patient complained of constant pain in the head, and could not lie with the occipital region on the pillow. It was difficult to arouse him, but he was rational when spoken to loudly. Urine and fæces were passed.

December 4th, he was transferred to the care of another surgeon.

"December 5th, patient was rather restless yesterday, getting up and wandering about the building; there is some mental impairment. His replies to questions are irrational; he is easily confused, does not recognize his surroundings or attendants. He admits that he has headache, although he does not complain; is rather drowsy and spends most of the time in sleeping. The bowels were well opened by repeated doses of magnesium sulphate. He is rather brighter to-day, more quiet. There is no muscular impairment. Pupils normal. Tongue slightly coated. Pulse good, rather full, regular. No fever. Marks of contusion about left ear and occipital region of scalp. Treatment: Rest in bed; potassium bromide, gr. xx., four times a day. Ice bag to head. Milk diet.

"December 6th, better; more quiet and rational. Mind, however, not entirely clear. Bromide continued.

"December 8th, improving slowly; mind still clouded. Treatment continued.

"December 14th, improving slowly; is strong physically, but the mind is still impaired. Still has some headache. Treatment continued.

"December 16th, about the same. Mind continues impaired. His talk is rambling and foolish. Last night he got up in the nurse's absence, and was found wandering about the building. Appetite and digestion good. Bowels regular. Spends the greater part of the time in sleep. When closely questioned he says he has headache, but he does not complain unless questioned. No signs of contusion about the scalp except slight discoloration behind the left ear. Bromide continued. He was placed in small ward with two other patients, and the doors and windows were secured so that he could not wander about.

"December 23d, there is very little if any mental impairment. Is up and about under charge of attendant. General condition good. Bromide continued.

"December 31st, mental condition slightly improved. Is regaining memory and is now conscious of his whereabouts. Medicine stopped. To-day placed in general ward.

"January 4th, mental condition greatly improved; is rational and conscious of his surroundings, but memory is still impaired. General condition good."

January 5th he was discharged, having been under treatment thirty-three days. An interval of two months passed, during which he attracted no special notice in the place he lived, being able to take care of himself, though his associates remarked about him that he was never "quite the same" as before the accident.

On March 9, 1897, he was brought to this hospital in a small pushcart, with a history of having been found lying unconscious on the sidewalk in the street. Being a very small man, not more than five feet in height, he was taken up in the arms of one of the nurses and carried into the ward. A thick dark stream of blood was oozing from the left external auditory meatus and running down his cheek, collar, and coat. He was unconscious, there was a strong odor of alcohol about his breath. Pulse, 64, regular; respiration, 18. Pupils normal, reacting slightly to light stimulus. There was no perceptible mark of injury to the head. As he was being undressed he partially regained consciousness, and, looking from one to the other of the people about his bed, he said very distinctly, "I am a poor old sailorman, and wouldn't harm any one." As soon as his clothes were removed he was placed in bed with the head slightly elevated. By this time, some ten minutes after his admission, he could be aroused by a loud voice, but he began slowly to pass into a deeply comatose condition. His pulse and breathing became slow and irregular; the pupils were somewhat contracted, not reacting to light, but were even. The blood continued oozing slowly from the left ear. About 3.30 P.M. swelling and bogginess were perceptible about the left mastoid and occipital regions. At 4 P.M. he began to gasp and choke as if some foreign body had gotten in the pharynx, and ejected from his mouth and throat a mass that might equal six or seven ounces (of blood clots) The ear still continued to ooze, and at intervals of about three-quarters of an hour he ejected quantities of clotted blood. At 9 P.M. he ceased to breathe.

Necropsy, performed seventeen hours after death: On reflexing the scalp the parts about the left mastoid and occipital regions were seen to be infiltrated with dark semifluid blood. On removing this there was plainly seen a horizontal fracture in the mastoid portion of the temporal bone, extending backward horizontally through the occipital bone almost to its centre. The skull cap was removed after being carefully sawed through, and the dura mater raised. The whole left hemisphere was covered by a thick, well-formed clot, thickest over the petrous portion of the temporal bone, leaving a marked depression in the brain substance when it was removed. The brain was now lifted out and the dura mater removed from the fossæ; then, by introducing the handle of the scalpel into the external fracture in the mastoid and making gentle prying movements, the fracture could be traced by the blood caused to well up along its track, which passed horizontally backward across the occipital bone to near the protuberance, and forward across the middle fossa through the petrous portion of the temporal bone, through the greater wing of the sphenoid to somewhere in the neighborhood of the foramen ovale.

Remarks: We have here a case involving some especial points of interest. In the first place it is fairly reasonable to conclude that there was fracture at the base of the skull on the first admission, though hemorrhage from the ear alone after injury to the head is not necessarily surely symptomatic of fracture, unless it is prolonged for several days. The ear bleeding, in conjunction with the swelling, coming on some hours after the injury, the pain and mental condition described in the history of the case, tend strongly to this conclusion. Adding to this the fact that the man is of short, slight build, and also the statements of those who saw him fall as he was walking on the pavement before his first admission, and considering

the extent of the injury shown at the necropsy, there must have been a fracture already existing at the time of his second fall. In the "International Encyclopædia of Surgery,"[1] edited by John Ashhurst, Jr., M.D., it is stated that "even months or years after a fracture at the base no attempt at union may be found, while in other cases the union may be merely by fibrous tissue or partly a thin plate of bone, partly membrane."

The immediate effects of fractures of the skull are the same as those from a solution of continuity in any bone, viz., rupture of blood-vessels, of the sinus of the diploë, of the middle meningeal artery, effusion of blood, separation or tearing of the pericranium and of the dura matér—phenomena that, owing to the nature of the parts where they have occurred, take on a most serious character, and become not so much complications as new diseases, much more disquieting than the lesion which they have followed—such as compression of the brain substance by blood, pus, fragments of bone, or wounds of the brain itself by spiculæ of bone; and there is also the probability of meningitis or encephalitis arising subsequently.

In this case, unfortunately, the idea of examining the vessels about the seat of fracture that had given rise to the hemorrhage did not suggest itself until the dura mater had been disturbed, but the immediate cause of death was the large effusion on the brain substance.

In these cases absolute rest is recommended as treatment, to prevent injury to the adjoining parts by the movement communicated to the fractured bone, and secondarily to ward off the possibility of inflammation of the brain or its membrane.

From the greatly lessened danger of wound infection in the present state of asepticism and our advanced knowledge in brain surgery, the use of the trephine for the relief of pressure from hemorrhage following a fracture is suggested as a surgical procedure which in such cases might be practicable for good. In the first half of the present century effusion following fracture was given among the causes calling for the use of that instrument.[2] But later it was discontinued by the experience particularly of Desault, who found it unsuccessful; and in Nélaton's "Pathologie Chirurgicale," Paris, 1847, tome ii., p. 597 ("Affections Traumatiques de la Tête"), the author states that of sixteen trephinings for traumatic effusions not one was successful. On the same page, however, he gives the following advice: "This operation is only rationally indicated in the cases in which a wound of the scalp exists with the fracture and the hemiplegia indicates the existence of an effusion at the seat of fracture. In these cases the air can reach the seat of fracture, and the trephine adds but little to the already existing dangers." Now our improved aseptic surgical technique should make this view have much less weight than at the time this advice was written.

As to the extent of operative interference that may sometimes be undertaken with a successful result in these injuries, and even in the days when asepticism played but a small rôle, the following case is quoted from the above-mentioned classical work of Boyer, p. 71, vol. v.: "Dionis relates in his 'Cours d'Opérations' that a man, falling from his horse, struck his head on the pavement and remained unconscious. The surgeon found on the frontal bone, which was fractured, a wound which he dilated sufficiently to apply the trephine. This operation, performed the day after the fall, produced no change in the sick man's condition, who still remained unconscious. Three days after this a swelling appeared on the occipital bone. Dionis opened this and discovered a fracture by contrecoup in this bone. A trephine was applied in this neighborhood, and a great deal of blood came out from the two openings in the cranium, which brought about a perfect recovery."

We might conclude these remarks with the advice of the famous French surgeon to his class: "Above all, gentlemen, do no harm."

EXFOLIATION OF THE MUCOUS MEMBRANE OF THE ŒSOPHAGUS AND PART OF THE STOMACH IN A COMPLETE CAST AFTER CORROSIVE POISONING.

By J. C. BROWN, M.D.,

[illegible], PA.

On the 27th day of April, 1897, I was called out in the country about four miles. I found on my arrival, about 5 P.M., a Mr. B——, thirty-two years old, about six feet in height, strong and robust. He had a rather anxious expression and was unable to speak above a loud whisper, but said he had no pain to speak of. His temperature was 100° F.; pulse, 110.

Upon opening the mouth I found the mucous membrane falling in shreds from every part of the mouth and pharynx, excepting about an inch of the anterior part of the tongue and about the same of the anterior part of the roof of the mouth.

He told me that on the previous day about 10 A.M., while walking along the road, he found a bottle containing what he supposed to be whiskey and drank it; that he immediately experienced a burning sensation in the mouth and throat, and was taken intensely sick at his stomach; that he went into a barn, where he remained until the next morning, and that he vomited and retched nearly all of the remainder of that day and all night, being unable to swallow anything after he had taken the contents of the bottle; that he came to a hotel in Smethport in the morning about 6 A.M. and went to bed, where he remained until about noon; that he then got up and walked home, a distance of about two miles over a steep hill, and that he stopped on the way at springs and tried to drink but could not swallow a drop.

Now, of course, seeing the condition of the mouth, I knew that if the material which caused it was also taken into the stomach there must be a great deal of destruction of mucous membrane, but I had only his word for it, and did not know but he might be mistaken as to swallowing it; besides, the symptoms did not indicate the same condition extending into the stomach; therefore I could say nothing as to prognosis.

I left a mouth wash containing tannic acid and antiseptics, also an antiseptic solution to use with the atomizer. I ordered milk and white of egg alternated with extract of beef by enema once in four or five hours and rubbing with alcohol three or four times daily, and said I would see him the following day if I did not hear from them. The next day I received word that he was somewhat better and had been able to swallow some water.

On the 29th I was called and found that at the suggestion of his mother he had swallowed two teaspoonfuls of kerosene oil, which produced a great deal of nausea and vomiting; otherwise he was about the same as when last seen.

He continued in about this condition, the corroded portions of the mouth, of course, turning somewhat dark by the mouth wash, temperature ranging between 99° and 102° F., pulse between 80 and 120, spitting up a great deal of purulent material, sometimes mixed with blood, until the 7th of April, when from 2 A.M. until 5:30 A.M. he had very profuse hemorrhage, vomiting nearly a pint of blood every half-hour, so the nurses

said, until I saw him about 5:30 A.M. and gave him a hypodermic of one-fourth of a grain of morphine sulphate and one-thirtieth of a grain of strychnine nitrate, which seemed to control the hemorrhage pretty well. He had another hypodermic about 11 A.M.; there was not much hemorrhage during the day.

About 5 P.M. of the same day I called, and before I got into the house the patient's brother came to me, somewhat excited, and said that his brother had just vomited something very peculiar. He brought it to me, and at first sight I thought it was a blood clot, but after washing it I found it to be the mucous membrane and submucous tissue of the œsophagus and stomach, and it was afterward examined by Dr. H. U. Williams, pathologist in the University of Buffalo, and found to contain also a part of the muscular coat of the œsophagus. The œsophageal portion was in perfect shape with the exception of a few small holes which might have been made in the effort to expel it, which it was said was quite difficult.

The stomach portion was torn somewhat in strips, due perhaps to a more pronounced effect of the corrosive agent. The whole was about sixteen inches long. It can be seen in the museum of the University of Buffalo. After the vomiting of this membrane the hemorrhage continued very profuse for thirty-six hours and then stopped; there was no hemorrhage afterward. He could swallow after this, but we did not allow him to do so for three days, and then began by letting him swallow a few teaspoonfuls of chicken soup, then milk, and milk and brandy in small quantities, gradually increasing until on the fifteenth he was taking about a quart of milk in twenty-four hours beside some toast and one or two raw eggs, and of course all this time we kept up the enemata of milk and extract of beef, which, excepting once or twice, were well retained.

On the 18th of May we took him to the Buffalo General Hospital, where he was seen by Dr. Allen A. Jones. We brought him back the next day, he standing the ride very well, and he continued about the same until May 30th. I will say here that I was satisfied that the food which he was taking by the stomach was not being digested and I found afterward that it was simply passed on into the intestines, where it was stored for a time and then passed per rectum in about the same condition in which he took it. His brother said that at one time four or five quarts passed per rectum in an undigested condition. You will ask, why was anything given by the stomach? Simply because he craved it and retained it without distress, and, as death was inevitable, I thought we might just as well give it to him.

On the 30th of May I tried to introduce a tube into the stomach. I could get it down to within three or four inches of the stomach but no farther. I tried again on the following day with the same result, showing that contraction had already taken place at that point, and, as we must expect in such cases, I found afterward that it had contracted the whole length of the œsophagus.

After my visit on the 31st of May I did not see him again until the 10th of June, but heard from him frequently. I learned from his brother that on the 1st of June he began vomiting shreds of a brownish material, of very foul odor. This continued for two or three days, followed by a yellowish material still more foul smelling than the other, and lasted for a few days. I can form no opinion as to what this material was, as I have only the nurse's description of it. At this time the taking of food by the stomach had been stopped. He continued in this condition, gradually getting weaker, vomiting and retching a great deal, until he died on the 24th of June.

I was not allowed the opportunity of making a post-mortem, which would have been most interesting. The length of time which had elapsed after he had swallowed the material and his inability, feigned or otherwise, to tell us what he did with the bottle prevented our finding out just what the corrosive was.

Now, of course, corrosive poisoning is not an uncommon occurrence, but the interesting points to me are: What corrosive would bring about the separation of those structures to such a depth; and why did not death occur from hemorrhage during or after the separation of those membranes? Again, how was he able to take such a large amount of material into the stomach without distress?

I forgot to mention that while he could perform the act of swallowing satisfactorily from the time he vomited the cast up to within two weeks of his death, fluids nearly always produced coughing, owing, I think, to the partial destruction of the epiglottis allowing some of the fluid to trickle into the larynx. I should have made an effort to keep the œsophagus open had I not been satisfied that the stomach was also destroyed, as far as its digestive function was concerned.

Perhaps it would not be out of place to state that this patient suffered a great deal with hiccough, and I found that it could be stopped nearly always by pressing the tongue, as in an examination of the pharynx, and holding it down twenty or thirty seconds; then it would be sometimes an hour and sometimes several hours before another paroxysm.

TWO COMPLICATED ABDOMINAL HYSTERECTOMIES.[1]

BY AUGUSTIN H. GOELET, M.D.,

NEW YORK,

PROFESSOR OF GYNÆCOLOGY IN THE NEW YORK SCHOOL OF CLINICAL MEDICINE.

These cases are particularly interesting on account of the difficulties encountered in removing the specimens here presented.

The first patient, Miss F——, aged twenty-three years, was referred to me by Dr. S. P. Cahen, of this city, under whose care she had been for several years, during which time she had a severe and prolonged attack of pelvic peritonitis following a short time after dilatation and curettage for dysmenorrhœa. When she first came under my observation in November last she had a daily temperature ranging from 100° to 104° F., which she had been having for a month or more, and she was emaciated and suffered constant pain. At that time it was impossible to make a satisfactory examination, but the whole pelvis appeared to be a mass of exudation, including the whole pelvic contents. She was put upon daily applications of faradization and immediately experienced relief. After a few weeks the temperature returned to the normal point and she had no further exacerbations. At this time examination showed that much of the exudation had been absorbed and the uterus, which was at first fixed, was somewhat movable and it could be outlined. On the left there was a mass of exudation sensitive to touch. On the right, where the exudation had to a great extent disappeared, neither the ovary nor the tube could be made out. The specimen shows them glued to the front of the fundus.

The condition at this time pointed strongly to the necessity for an abdominal operation and the subsequent treatment was instituted with that end in view. The faradization was continued three or four times each week and she was put upon tonics and a nutri-

[1] Presented at the May meeting of the New York Medico-Surgical Society.

tious diet. She improved steadily and soon began to feel that she could resume her duties.

She entered my sanatorium April 5th, and on the 6th the operation was performed. On opening the abdomen marked congestion of the peritoneal vessels was noticed and the intestines were adherent everywhere to the lower region of the abdominal wall, to the sides of the pelvis, and to the uterus and bladder. These were separated with great difficulty, particularly those posterior to the uterus, and those binding the sigmoid flexure to the mass on the left of the uterus. In separating the adhesions at this point the gut was opened, but it was promptly closed by Lembert sutures. Subsequently an abscess was broken into, which proved to be an ovarian abscess. This constituted the mass on the left, surrounded by a thick wall of exudation.

The tube and ovary on the right, as the specimen shows, were folded over on the front of the fundus and were fastened firmly there by dense adhesions. Several small cysts in this mass were ruptured in separating the adherent loops of intestines. At once it was seen that removal of the uterus with both masses was imperative.

To shorten the operation, which had already consumed considerable time, supravaginal amputation was done and the cervix left. The pelvis was flushed with normal salt solution, which was permitted to remain on closing the abdomen. Something over two hours was consumed in completing the operation, and the patient was gotten to bed in a fairly good condition. The highest temperature for the first four days was 100° F. On the morning of the fifth day the temperature was 99° F., but the dressing was found to be soiled by pus which was oozing from the lower angle of the abdominal wound. An opening was made in the posterior cul-de-sac of the vagina and a considerable amount of pus was evacuated. A drainage tube was inserted through the vaginal incision, and the lower angle of the abdominal wound was opened and a drainage tube inserted into the pelvis. Through-and-through irrigation with bichloride solution was thoroughly done. The temperature at once dropped to 98° F.

General sepsis was at this time manifest, but she improved very much for the first few days after this. On the third day after, however (the eighth day after the operation), she had a sharp chill and the temperature jumped up to 105° F. She continued to sink from overwhelming sepsis in spite of good drainage and repeated irrigation, and died April 19th, thirteen days after the operation.

The autopsy showed that the abdominal wound was healed except at the lower angle where the drainage tube was inserted; the pelvic roof was also healed, as had the wound in the intestine, but a perforation of the gut was found a short distance from the rent. This probably occurred because of some thin point in the wall of the gut, left where the adhesions were separated.

The other patient, Miss R——, aged forty-four years, was referred to me by Dr. Grace Pulver, of Torrington, Conn. In December she had a pelvic peritonitis and again in February of this year she had another attack. Following this there was an intermittent bloody discharge from the uterus, which at times amounted to a sharp hemorrhage. During this time she had acute exacerbations of fever, and later the discharge became offensive. March 17th of this year she entered my sanatorium and two days later an examination was made under anæsthesia. The uterus was partially fixed and to the left there was a mass involving the tube and ovary on that side. On the right the appendages appeared to be normal. A thorough curettage was done and the scrapings were preserved for microscopical examination. The uterus was soft and easily dilatable, and the endometrium was broken down and spongy.

She improved very much after the curettage, the bleeding ceased, and there was no return of the increased temperature from which she had been suffering for so long a time previously. But the microscopical examination showed that the uterus was the seat of adeno-carcinoma and a hysterectomy was therefore decided upon.

The operation was done April 7th. On opening the abdomen the intestines were found to be adherent everywhere to the pelvic organs. The adhesions to the uterus and bladder were easily separated, but those binding the intestines to the mass involving the left broad ligament were very firm and unyielding. A small abscess in the mass was invaded in the process of enucleation, but with care infection of the peritoneum was avoided The mass, which was soft and friable in places, was firmly attached to the left posterior wall of the pelvis in close proximity to the ureter, and was with difficulty removed. After getting it free from the pelvic wall the uterus was removed in the following manner, viz.: the left uterine artery was tied and divided after incising the peritoneal covering of the uterus in front and behind and stripping it down. The cervix was then separated from the vagina at the cervico-vaginal fold all around; then the right uterine artery was clamped and divided between the clamp and the uterus; next the round ligament with its vessel was clamped and divided close to the uterus; and finally the right ovarian artery was clamped and divided and the uterus with the mass was lifted out. This left a clear field for tying off the vessels on the right. The vaginal vault and pelvic roof were closed by a continuous suture of fine chromicized catgut and no drainage was employed.

The patient was lowered from the Trendelenburg posture, and the pelvic cavity was flushed with warm decinormal salt solution and the abdomen closed. The operation consumed something more than an hour.

The highest temperature recorded after the operation was 100° F., on the fifth day. The abdominal sutures were removed on the fourteenth day. The patient has made an uneventful recovery without a single complication.

The question may be raised why the vaginal route was not utilized for removing these two uteri, since it has many points of advantage over the abdominal route in certain cases. In the first case a hysterectomy was not thought to be necessary until the abdomen was opened, and, could it have been decided before, the adhesions to the bowels were too extensive and firm to admit of a safe and satisfactory vaginal hysterectomy. In such cases, even if the organ and diseased appendages can be gotten away safely through the vagina, the greater liability to fresh adhesions to the bladder and stumps of the broad ligaments would offer a strong argument against it. I have been obliged to open the abdomen several times to do away with adhesions following vaginal hysterectomy, which were causing most intense suffering. I believe that adhesions occur more frequently after vaginal than after abdominal hysterectomy, because the pelvic vault is not closed perfectly, and frequently extensive raw surfaces are left exposed to contact with the intestines which prolapse into the empty pelvis.

In the second case there was involvement of the broad ligament on the left, which pointed strongly to cancer and more perfect removal could be accomplished through the abdomen.

1 West Seventy-first Street.

Before operation a good night's sleep is of the greatest value to both patient and operator.

Society Reports.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, September 27, 1897.

LANDON CARTER GRAY, M.D., PRESIDENT.

Nominations.—*President*, Drs. Henry Dwight Chapin and A. M. Jacobus; *First Vice-President*, Drs. J. Riddle Goffe, Wickes Washburne, and N. E. Brill; *Second Vice-President*, Drs. R. P. Lincoln and B. F. Curtis; *Secretary*, Dr. Charles H. Avery; *Assistant Secretary*, Dr. W. E. Bullard; *Treasurer*, Dr. John S. Warren; *Censors*, Drs. H. L. Collyer, F. M. Crandall, E. Fraenkel, M. J. Burstein, Whitehead Gilfillan, L. C. Gray, W. L. Carr, F. H. Daniels, R. A. Murray (declined), W. Stevens, S. D. Powell, and J. L. Barton.

Certain Sources of Neurosis in Woman.—DR. EGBERT H. GRANDIN read a paper with this title. The term "neurosis," he said, was of necessity a very vague one, and often was a mere cloak for ignorance. This ignorance was sometimes due to faulty examination, and sometimes to the fact that a specialist had been consulted who had confined his search to the narrow limits of his particular branch. The following cases were cited by way of illustration:

Fissure at Neck of Bladder.—A married woman came to him with the statement that sexual intercourse was impossible. The woman was intensely neurotic, and she complained of pain in nearly every portion of the body. Digital examination showed the pelvic organs apparently normal; there was not even a prolapse of the ovaries, as had been suspected. On examination of the neck of the bladder a fissure was found. Dilatation and the application of phenic acid cured the case.

Adhesions of Clitoris.—It should be remembered that the clitoris exerts a powerful influence in the production of various neuroses. Many a case of nymphomania and masturbation would find its explanation in adhesions of the clitoris. For example, a lady of thirty-five had consulted him for the relief of an intolerable pruritus of the vagina. Sugar was absent from the urine, and many remedies had been tried in vain. The prepuce of the clitoris was firmly adherent, and there was a collection of smegma. Removal of these adhesions effected a prompt cure.

Anal Fissure.—The speaker said that he was inclined to think that the rôle of the sphincter ani was not appreciated so fully as it should be as a factor in disease. Fissure of the anus was a common cause of reflex irritation; hence the rectum and anus, as well as the vagina and pelvis, should be subjected to careful scrutiny. For instance, an intensely neurotic lady had consulted him after two years of married life, because of menorrhagia and intense dyspareunia. The spasm of the hymen was so great that the vaginal examination could be made only under anæsthesia. Inspection of the rectum showed a deep ulcer. The sphincter ani was dilated and the ulcer cauterized. She made a rapid recovery.

Coccygodynia. The coccyx is a relatively frequent source of neurosis, because of the liability of the coccyx to be injured, not only during labor but by falls on the back. Fracture of the coccyx, even though caries does not result, often causes pressure on the nerve filaments, and hence reflex irritation. In seven cases he had removed the coccyx because of actual disease or because a fracture accounted for reflex nervous phenomena not otherwise explained. In every instance the operation had brought the desired relief. In the operation for the extirpation of the coccyx, he would insist that drainage was unnecessary, assertions to the contrary notwithstanding. After the removal of the bone, with a large curved Hagedorn needle the suture could be made to travel entirely around the wound, which could thus be easily and completely closed.

Diseased Uterine Appendages.—The speaker then took up the consideration of the part played in the production of neuroses by disease of the tubes and ovaries. He remarked incidentally that he looked upon menstruation as the most obscure of all the feminine neuroses. A woman of about thirty-five had been brought to him by her husband from a retreat for the insane, where she had been placed by a neurologist. She exhibited deep melancholia, erotomania, and suicidal tendencies. Examination showed perimetritis and endometritis, and the husband was told that these findings did not necessarily account for her condition. Nevertheless, the appendages were removed by laparotomy, and the woman was completely cured, although they were not markedly diseased. This was an example of empirical operating. Another patient, suffering from hystero-epilepsy, had such violent attacks that anæsthesia was necessary to control them. It was ascertained that these attacks occurred chiefly at the menstrual period; hence in an empirical way the removal of the appendages was advised. The operation was performed about three years ago. After the operation the attacks diminished in frequency and severity, and there had been no attack for the last two years. The organs were found to be infantile in type. The next case was cited as an example of the failures following empirical operating. The patient, a woman of thirty, married to a man of fifty, suffered from hystero-epilepsy. Examination showed the appendages to be markedly enlarged but freely movable. There was no evidence of increase of the symptoms at the menstrual periods. The operation was requested, on the ground that everything else had failed. It was performed, and the attacks diminished for a few months; then a pseudo-menstrual flux appeared and the attacks returned as before. The case was unquestionably one of essential epilepsy, and the result was what was to be expected. In conclusion, the reader of the paper entered a plea for a more careful examination of the body as a whole, before concentrating the attention on one set of special organs.

DR. ROBERT A. MURRAY congratulated the reader of the paper on having presented so many facts in proof of the frequency of faulty diagnoses. He could cite from his own experience many similar examples, all of which only served to emphasize the tendency to overlook minor abnormalites while searching for grave pathological lesions.

DR. H. N. VINEBERG said that he was surprised that in the first case reported the neck of the bladder had been examined without the existence of symptoms pointing to some affection there, for certainly this would not be generally done by the practitioner. He was inclined to be sceptical regarding the part played by clitoridal adhesions in the production of neuroses—at least, the tendency was to overdo this matter and too hastily conclude that these were responsible for the symptoms present. The majority of cases with reflex nervous symptoms would be made worse by the removal of the tubes and ovaries, unless there was evidence of a distinctly pathological state of these organs. When such a condition existed and it was considered justifiable to operate, the uterus as well as the tubes and ovaries should be removed. Regarding incomplete sexual commerce, he said that it was often observed in married women who had borne a number of children that they began to suffer from various neurotic symptoms. Inquiry would frequently elicit the fact that the woman made no effort to prevent conception but that the husband practised "withdrawal."

Dr. C. A. Von Ramdohr said that laceration of the cervix not infrequently gave rise to epilepsy. He had seen a number of cases in which the simple closure of the everted cervix cured an epilepsy which had not been diagnosticated as hystero-epilepsy until after a thorough examination. He also referred to those neuroses occurring during confinement, in which there was no obliteration of the cervix, and in which the cause was to be found in a fissure of the urethra, anus, or vulva, or possibly in an abnormality of the coccyx.

True Epilepsy Never Cured by Operations.—Dr. Louis Faugères Bishop said that epilepsy was a disease of the motor cells of the brain—a fact which should be borne in mind in all efforts to cure it by attacking certain regions of the body. He did not think true epilepsy had ever been cured by operations or by local means. Postoperative neurasthenia was a very common condition, and should receive thoughtful consideration by the surgeon before he decided too hastily to operate upon neurotic individuals.

Dr. H. L. Collyer said that he had seen three cases presenting no bladder symptoms, and yet examination readily revealed fissure of the vesical neck. As to adhesions of the clitoris, it should be remembered that there was hardly one woman in a hundred who did not have such adhesions. The effect was similar to that observed in the male from similar adhesions. The great sensitiveness of the clitoris was well shown by the struggling produced by an attempt to separate the adhesions unless the patient was very deeply anæsthetized.

Dr. W. M. Leszynsky referred to the removal of the healthy ovaries for the cure of epilepsy or insanity. He had written an article upon this subject some ten or twelve years ago, and hence was greatly astonished very recently to find two cases in which such an operation had been performed. The practice, in his opinion, was not only not justifiable, but was positively criminal.

Neurologists Sceptical about Pelvic Disease Causing Epilepsy.—Dr. L. C. Gray said that he fully believed, with the reader of the paper, that a neurosis was a very indefinite thing, with the exception of epilepsy. Epilepsy had a certain definite group of symptoms which marked it as something apart, although we knew very little of the causes of it in the so-called idiopathic variety. All the vague nervous symptoms occurring so frequently in women from disease of the pelvic viscera could hardly be called a neurosis, in the meaning that we could always recognize the cause by the symptoms. It had always been his custom to assume that a case of true epilepsy—an absolute loss of consciousness, with or without clonic and tonic convulsions—could not be caused by disease of any of the pelvic viscera, simply because there had been no proof adduced that such a cause could bring about such an effect. Future study might bring forward such proof. Neurologists were becoming more and more sceptical regarding epilepsy resulting from disease of the pelvic viscera. But there were many forms of neurasthenia, and many more or less vague neuralgias, together with the manifold phenomena of hysteria, in which the cause could be found in some disturbance of the pelvic viscera. In every case in which a positive diagnosis of epilepsy could not be made, it was well to have the patient examined by a competent gynæcologist. He was sorry to say that he had himself repeatedly treated without success cases which were afterward promptly cured by appropriate treatment directed to the pelvic organs. As to the removal of the ovaries and Fallopian tubes in hysterical and epileptic cases, he had never yet seen it do more than temporary good, provided, of course, the tubes and ovaries were healthy. He recalled one case in which a prominent gynæcologist of this city had removed one ovary because of vomiting. This had given relief for a time, but the vomiting had returned, and he had then removed the other ovary. Again there had been relief for a few months, and on the return of the vomiting the gynæcologist had once more operated, separating some adhesions. When the patient had again relapsed, she had been referred to him. She was a perfectly typical case of hysteria, and, although she asserted that she vomited constantly and had been unable to retain food for weeks, he did not believe her. She was followed, and was seen to walk through the street complacently eating peanuts.

Dr. Grandin, in closing the discussion, said that he was not prepared to say that in the first case cited there had been no bladder symptoms, but if they had existed they had been masked by the uterine symptoms. If more general practitioners looked to the clitoris, even at birth, it was not improbable that fewer cases would go to the neurologist or to the gynæcologist in later life. He was thoroughly convinced that adherent prepuce of the clitoris was responsible for many nervous manifestations in women, which would even simulate actual disease of the uterus, tubes, or ovaries. He could have cited at least fifteen or twenty such cases from his records. He was firmly convinced that at the birth of the female infant, the physician should look out for preputial adhesions of the clitoris, even as it was the custom now for the careful physician to look for similar trouble in the male infant.

Retrodeviations of the Uterus.—Dr. Eugene Coleman Savidge read this paper, and called attention to the fact that all pelvic suppurations were excluded from consideration. He said that this malady, called after one of its most prominent symptoms, was one of the most common of female ills. It was always a symptom of enfeebled muscular power, and almost always an accompaniment of downward displacement of the abdominal viscera. It was evident, therefore, that it should not be treated as an isolated mechanical condition. As to its frequency, several authors had asserted that about twenty per cent. of women suffered from it. It was found in two hundred and forty out of one thousand cases coming to him for gynæcological treatment. In about eighty or ninety per cent. of the cases the displacement could not be permanently reduced. The treatment should be directed to the relief of the congestion and strengthening the muscular power. When vitality and muscular power failed, there would be a return of the congestion and also of the former symptoms. In a case of non-adherent and uncomplicated retrodeviation, the surgeon would do an Alexander's operation. In a paper read by Dr. George M. Edebohls before the Geneva congress, it was stated that out of one hundred and fifteen Alexander operations, seventy-seven had been "anatomical successes;" the remaining thirty-eight cases showed an instructive list of hernias, failures, and mishaps of various kinds. As about twenty-five cases of movable kidney developed after the operation, it would now be in order to suggest that the next modification of the Alexander operation should be the sewing of the kidney to the abdominal wall. The author's views of the conditions underlying retrodeviation of the uterus may be briefly stated as follows: (1) Passive congestion and an engorged venous system lead to renal and arterial changes which materially shorten life; (2) enfeebled muscle is readily stretched; (3) in addition to the columnar base of the vagina, the uterus has eight ligaments for its support, and these ligaments depend for much of their power upon the muscular fibres from the muscular coat of the uterus, and these fibres partake of the health of the uterus; and (4) general muscular and vital debility bring about passive congestion—in a word, the subject may be said

to be comprised in the reciprocal relation of congestion and muscular debility. In addition to the time-honored routine treatment, the speaker said, markedly beneficial results would follow the persistent use of diuretics, combined with iron and digitalis. Outdoor exercise and daily massage and baths were all of service. After two or three months of such treatment, all the symptoms usually disappeared, but the patient should be told that the same causes would bring about a return of the symptoms.

Uterine Fixation, Not Displacement, the Chief Factor.—Dr. W. Gill Wylie said that about fifteen years ago he had made a careful study of the dynamics of the pelvis, with very much the same results as had been given in the paper. He was of the opinion that many of the cases under consideration were the result of imperfect development, and that too much attention had been given to the mere mechanical displacement. He had never opened the abdomen for the purpose of correcting the uterine displacement, although he had devised an operation for shortening the round ligaments in cases in which the abdomen had been opened for some other reason. He had never been able to convince himself that it was right to fix the uterus to the abdominal wall. It was not the mechanical displacement, but the fixation of the uterus, which gave rise to the troublesome symptoms.

Every Displacement does Not Demand Treatment.—Dr. Paul F. Mundé said that the subject had been presented in a very novel and original manner, and the author's facile pen had almost convinced him that he really meant all that he had said. The author had ridiculed the methods of the gynæcologist and the abdominal surgeon, and had even made it appear that the gynæcologist knew very little about medicine. He agreed thoroughly with him when he mentioned methods of prevention, but he wished him to state how he was going to carry out these methods. It was right in theory, but impossible in practice. For example, as a prevention of subinvolution he had himself many years ago recommended that every parturient woman should have a pessary introduced before she was allowed to get out of bed. It was a nuisance, of course, but so was a crutch; yet it was useful and at times desirable. He would like to put himself on record once more as saying that he did not think that every displacement of the uterus produced symptoms or required treatment. In many cases he was sure that the backache complained of was not dependent upon the retrodisplacement, but upon the uterine catarrh and chronic congestion, with the consequent dragging upon the ligaments. Nevertheless, he believed that a retrodeviation of a major degree should be remedied when detected, because sooner or later it would produce unpleasant symptoms. He would even apply this rule to some young single women.

Nothing New in the Paper, and Its Teaching Dangerous.—Dr. George M. Edebohls said that such a paper as this certainly did no good, and might be productive of a good deal of harm. There was absolutely nothing new in the paper, although the facts had been presented in a very felicitous manner. It left us where we were ten or fifteen years ago. Prevention was, of course, most desirable if practicable, but it could be carried out only within narrow limits. Even if some women were restored to good health, there was still a class of cases which must be put under what the author had very happily termed "recurring treatment." The speaker said that one of his recent papers had been referred to by the author, but it had been apparently misquoted, for out of the one hundred and fifteen cases there were, if his memory served him, at least one hundred and five satisfactory anatomical cures, and in these cases his observations had extended over an average period of sixteen months.

Dr. Vineberg protested against the criticisms made in the paper concerning the operative work of modern gynæcologists. Either the reader of the paper was not serious, or else he was not sincere. It seemed to him that the keynote of the whole paper was intended to be renal insufficiency. As to the part played by the general health, he would say that, although he was visiting physician to a home for chronic invalids, he found very little occasion to treat uterine displacements among the inmates. It was a mistake to suppose that renal insufficiency, heart disease, or lung disease would produce marked disease or displacement of the uterus. He thoroughly indorsed the statement made by Dr. Mundé, that when there was marked retrodisplacement it was pretty sure in time to cause trouble.

Dr. Julius Rosenberg said that the symptoms of which the patients complained often persisted after the correction of the displacement. In a small percentage of cases operations were necessary, but this percentage was growing steadily smaller.

Dr. Savidge, in closing the discussion, said that he did not in any way give renal insufficiency as a cause of retroversion, nor was he a disparager of the Alexander operation. He had in his hand the paper of Dr. Edebohls, and thought he had quoted the figures correctly. In proof of this, he proceeded to read the results from the tables there given.

Therapeutic Hints.

Hypodermic Purgative.—

℞ Caffeine and chloral ..... āā gr. viiss.
Water ..... ℥ lxxv.
M. Inject fifteen minims.

—Ewald, *Journal de Médecine de Paris.*

Cough Mixtures.—Dr. James K. Crook says that the following formulas have been thoroughly tested in both hospital and private practice and render good service in suitable cases. For irritative coughs:

℞ Phenacetin ..... gr. xx.–xl.
Ext. glycyrrhizæ ..... gr. xx.
Sacch. albi ..... ʒ ij.
Fiat pulvis, in chartulas 20 dividendus. S. One to be taken at one, two, or three hour intervals.

For the same of more obstinate character:

℞ Phenacetin ..... gr. l.
Ext. glycyrrhizæ ..... gr. xx.
Codeinæ sulphatis ..... gr. ij.–iv.
Sacch. albi ..... ʒ ij.
Fiat pulvis, in chartulas 20 dividendus. S. One to be taken every two, three, or four hours.

℞ Ammonii carbonatis ..... ʒ ij.
Acidi salicylici ..... ʒ iiss.
Aquæ cinnamomi ..... āā ʒ ij.
M. S. Teaspoonful in a little water every three hours

—Henry R. Slack.

Carcinoma.—Although local treatment is useless in carcinoma, in cases of doubt, as when there is ulceration or fissure, the following ointment is useful. If healing does not take place in two weeks operate, as carcinoma never heals in this way.

℞ Balsam. peruvian. ..... āā ʒ i.
Unguent. hydrargyri nitratis ..... āā ʒ i.
Petrolati ..... ʒ i.
M

—J. H. Hearn.

Use of the Stomach Tube.—Dr. Murdoch (*New York Medical Journal*, vol. lxv., No. 3) says the tube should be used: 1. For diagnostic purposes. An hour after a test meal the contents of the stomach are with-

drawn by the tube and examined for hydrochloric and other acids, peptone, etc. 2. To empty the stomach in poisoning except when due to caustic alkalies, because of the danger of perforation. 3. For lavage. In stagnation of food in the stomach, in accumulations of large amounts of mucus, and sometimes in simple glandular atony with lack of hydrochloric acid. Its best results are obtained in dilatation of the stomach by cleansing the mucous membrane of stale food and mucus, and restoring the vitality of the secretory glands. It should not be used in acute and semi-chronic gastric disturbances, and is positively contra-indicated in: 1, thoracic aneurism; 2, serious cardiac disease; 3, recent bleeding from any part; 4, great debility or advanced age; 5, gastric ulcer.

Tapeworm.—

℞ Olei terebinthinæ,
Oleoresinæ filicis maris.....āā ʒ vi.
Mucilag. acaciæ..... ʒ ij.
M. ft. emulsion. S. Day before treatment, a milk or thin-soup diet, and one drachm of compound jalap powder. The emulsion is taken the following morning, fasting, and a half-hour later a dose of castor oil.

—F. A. A. Smith.

Expectorant.—

℞ Ext. glycyrrhizæ..... gr. xx.
Phenacetin ..... gr. xx.–xl.
Ammonii muriatis..... ʒ i.–ij.
Sacch. albi ..... ʒ ij.
M. et in chart. 20 dividendus. S. One powder to be taken in a little water every two, three, or four hours.

Purgative Pill.—

℞ Podophyllin,
Leptandrin,
Ext. colocynth. comp. .....āā ʒ i.
Ol. menth. pip..... gtt. vi.
M. ft. pil. No. 60. S. One for a laxative; two for a purgative, and three for a drastic effect.

—D. E. Ruff.

Antineuralgia Pill.—

℞ Strychninæ sulph ..... gr. i.
Quininæ sulph..... ʒ i.
Ferri redacti ..... gr. xv.
Ext. gentianæ..... ʒ ss.
M. ft. pil. No. 60. S. One three times a day.

This is especially good for facial and stomach neuralgias. If there is a marked malarial element present, add arsenious acid, five grains, to the formula.—D. E. Ruff.

Garfield Tea.—The "Standard Formulary" gives the following as the approximate composition of "Garfield tea":

℞ Triticum..... ʒ i.
Liverwort ..... ʒ i.
Senna ..... ʒ viii.

Pulmonary Tuberculosis.—

℞ Creosote (beechwood)..... gr. 374
Camphor..... gr. 225
Aristol..... gr. 150
Eucalyptol ..... gr. 450
Sterilized neat's-foot oil..... ʒ 8
M. S. To be used as a hypodermic injection.

Each cubic centimetre of this solution contains a grain and a half of creosote, six-tenths of a grain of aristol, and three-quarters of a grain of eucalyptol.—Gilbert, *Pract. Drug. and Review of Reviews.*

Hæmatophilia.—All the observations which have been made upon the nature, history, and progress of this disease may be resolved into two essential and congenital conditions: an abnormal vitality of the blood, and a delicate construction of the capillaries. The circumstances of the disease appear to support the following propositions: 1. Its intermitting character. 2. The strong action of the arterial system, as shown by the mental excitement before the attack. 3. The immunity from excessive hemorrhage, even after wounds, in the intervals between the attacks. 4. The rare occurrence of bleedings in persons who have some steady outlet, as hemorrhoids. 5. The facility with which bleedings are sometimes prevented or arrested by means which lower the vitality of the blood, as diarrhœa or smart purging, etc. 6. The readiness with which ecchymoses form under the skin, from very trifling injuries.—Hopkins, *Occidental Medical Times*, March, 1897.

Vulvar Vegetations.—An active application is the following:

℞ Powdered savin,
Iodoform,
Salicylic acid.....āā equal parts.
M.

—Lutaud.

Nephritis.—

℞ Ergotini..... 5 gm.
Ac. gall..... 8 gm.
Extr. et pulv. rad. rhatan. q.s. ut ft. pil. nr. viginti.
S. Take one pill four times a day.

℞ Ergotini..... 2 gm.
Ac. gall..... 4 gm.
Saccharini ..... 0.05 cgm.
Muc. gumm. arab..... 200 gm.
M. S. Teaspoonful twice a day.

—Pulvirenti.

The Therapeutical Action of the Cold Bath in Typhoid Fever.—Drs. Robin and Binet (*Archives Générales de Médecine*, November, 1896) report after careful chemical investigations that the cold bath increases the amount of air inspired and expired and increases the amount of carbonic-acid gas excreted and the amount of oxygen absorbed. They conclude: 1. That in typhoid fever there is an exaggerated loss of nutrition, and large quantities of waste products as well as of ptomains invade the tissues, and are not excreted as fast as they are formed. These products are not split up, owing to the decreased absorption of oxygen. 2. That our aim in such cases should be to increase oxidation. 3. That cold baths have a remarkable oxidizing power. 4. That they increase the respiratory processes, but above all they increase the total amount of oxygen taken in and increase its absorption. 5. That the respiratory change does not begin to take place until half an hour after the bath and reaches its maximum at the end of an hour. 6. That the duration of the process cannot be sharply fixed. 7. That if the bath does not reduce the temperature it does not produce the above-mentioned change. The cold bath by diminishing the temperature lessens the increased tissue destruction and the production of toxins. Increased oxidation transforms the bacterial toxins into harmless, easily eliminable, soluble products. The cold bath raises the arterial tension and increases the heart action, from which causes diuresis recurs and the products of tissue change are more easily carried off. These effects are all due to a reflex action from the nervous system.

Hints for Patients on Sea Voyages.—Dr. George Walter Barber (*The British Medical Journal*, December 19, 1896) gives some good advice for patients sent away for the benefit of their health. In the first place a crowded ship should be avoided and an entire cabin should be secured, especially for phthisical patients. The cabin should be amidship, where the motion and vibration of the ship are least felt. The patient should wear a cummerbund over his pajamas, as the neglect of this precaution frequently leads to severe abdominal pain and diarrhœa, and often colitis, owing to the free perspiration which occurs in the tropics being checked by a stream of cold air from an open

port, etc. The patient should never sleep on deck, and as soon as he arrives in the tropics he should wear a solar tope as a protection against sunstroke, sun headache, and thermic fever. The patient should be told to keep on deck as much as possible, but should not sit under a single awning, which allows the sun's rays to penetrate. Clothing should be suited to the varying climates. All alcoholic subjects should be put under the ship's surgeon at the beginning of the voyage, as he is then able to make sure that they get no liquor. The morning bath should be taken warm by malarial subjects and those who are very delicate. Very strict orders should be given as to diet, most persons eating too much and exercising too little. Dr. Barber recommends the following for seasickness:

℞ Chloroformi purif. . . . . ℥ij
Tr. nuc. vom . . . . . ♏i.
Tr. lavand. . . . . ♏x.
Aq. . . . . ad ℥ i.

M. ft. mist. S. To be well shaken, and taken every hour until the nausea is relieved; liquor morphinæ acetatis, ♏ v., if there is much pain.

Alcohol is unnecessary in most cases; milk and soda, beef tea, or beef jelly should be given in small quantities at short intervals. A letter describing the case should be given the patient, which may be handed to the ship's surgeon if his services are required.

Surgical Suggestions.

Osteotomy of the Femur.—In the treatment of tuberculous disease of the hip in its early stages Dr. R. F. Tobin (*British Medical Journal*, April 24th) gives the following summary of his views: 1. That no treatment better than rest, combined with constitutional remedies, is known for tuberculous disease of the hip. 2. That a large proportion of cases of this disease, especially those in which flexion has occurred, go on to suppuration, and that one of the chief causes of their doing so is the difficulty of giving the joint rest. 3. That much of this difficulty lies in the fact that the position of greatest ease for the tuberculous hip-joint is one in which it is very awkward for the patient to carry the limb, very difficult for the surgeon to fix it, and therefore one in which the joint is constantly exposed to disturbance. 4. That it is possible, and in many cases advisable, to remove this difficulty by such an osteotomy of the femur as will allow the limb to be put straight, while the upper of the fragments retains "the natural position of rest." 5. That the operation also does good in some cases by relieving tension in the bone. 6. That an osteotomy of the femur when done in this respect is not so formidable an undertaking as it is under ordinary circumstances, for it is not the division of the bone that is formidable in this operation, but the constrained position in splints and the long period of rest required for union. Now since these latter incidents are a great gain for the tuberculous joint, they must be put to the credit of the operation, thus leaving very little to be entered on the debit side.

Treatment of Fractures.—Dr. Davis concludes an article in the *Annals of Surgery* as follows: 1. It is my belief that massage and passive motion are not used to the extent that they should be in the treatment of fractures. 2. That immobility of the fractured ends favors quick union with little deformity. 3. That there are some cases in which, owing either to peculiarities of the fracture or to the impaired constitution of the individual, the tendency to the formation of callus is marked. Motion in these tends to the formation of exuberant callus and deformity. 4. That there are others in which union is unduly delayed; disturbance of the fractured ends in these hinders union. 5. That it is wise to wait until the fractured parts are glued together, usually eight or ten days, before attempting any except the lightest massage, and any extensive passive motion after that time should be used carefully but diligently. 6. That passive motion and massage when first attempted should be of the most gentle character, and not so violent as to disturb the relation of the broken bones. 7. That any marked pain and inflammatory reaction following passive motion and massage are evidence that it has been too violent. 8. That the limb should receive massage and manipulation at each inspection or change of dressing, often daily. 9. That in some cases it is advisable to administer such massage as is possible without removing the splints. 10. The persistent stiffness, particularly in fractures or injuries of the wrist, is often due to a rheumatoid affection locating itself in the injured region. Massage is valuable in the treatment of such. 11. That massage should be given to that part of a limb beyond the seat of fracture, to preserve it in a normal condition. 12. That such dressings and methods of treatment should be adopted as will allow of the greatest use of massage and passive and active movements consistent with proper retention of the fragments.

Empyema of the Antrum.—In discussing a new operation for the cure of obstinate instances of disease of the antrum of Highmore, Dr. H. A. Lothrop (*Boston Medical and Surgical Journal*, May 13th) presents the following conclusions: That the relation of the openings of the accessory nasal cavities is not constant, and that fluid may gravitate from one to another according to the position of the head. That the antrum is a reservoir for pus, of primary or secondary origin. That many cases of empyema of the antrum are never cured; therefore further efforts are needed, which must be in the line of surgery. That the more radical operation with the idea of drainage have relieved cases hitherto incurable. That there are important objections to a large canine or alveolar opening with the idea of establishing permanent drainage. That permanent nasal drainage is less objectionable than oral drainage. That the removal of the lower half of the naso-antral wall prevents further pus retention and thereby allows the antral mucous membrane to resume a healthy condition. That the operation suggested is of short duration and not severe, although most radical. That, by this procedure, the antral cavity is rendered easily accessible to frequent irrigations by the patient and to local applications and occasional inspection by the surgeon.

Sprains of the Ankle-Joint.—As a result of massage in the treatment of twelve hundred and thirty-one cases of sprain of this joint, these deductions are made: 1. Prevent swelling or rapidly disperse it if present. 2. Prevent pain or quickly remove it when due, as it must be, to tension. 3. Prevent stiffness or overcome it when already present from disuse. 4. Prevent the sense of weakness and restore the part to its original vigor and strength. 5. Reduce the time of treatment from weeks to a corresponding number of days. 6. Permit the immediate use of the injured member.—Drs. Van Arsdale and Gallant.

The first strip for a sprain of the external malleolus is applied, beginning just above the ankle on the unaffected side of the foot, and ending on the affected side about half the way up the calf. This strip is usually alongside the tendo Achillis and makes firm support under the heel. The second strip starts on the inner side of the unaffected part of the foot, near the ball of the toe, comes around over the back of the heel, and ends about the base of the little toe. It

crosses the first one just above the border of the heel. The third strip overlaps the first half-way, the fourth the second, and so on until the part sprained is fully covered by this criss-cross strapping. A cheese-cloth bandage is applied more with the idea of securing close adhesion of the plaster and is removed within twenty-four hours. As soon as the dressing is completed the stocking and boot should be applied. The patient is now ready to begin walking, and this should be insisted upon in the presence of the surgeon. Direct him, for instance, to walk about the room eight or ten times. At the end of a week it is well to remove the strips and reapply in the same manner as above. Two or three such dressings suffice to complete the cure.—DENNIS' "Surgery," vol. ii., p. 362.

Correspondence.

OUR PARIS LETTER.

(From our Special Correspondent.)

HEALTH OF PARIS—EXOPHTHALMIC GOITRE—ITS BEST TREATMENT—THOMSEN'S DISEASE—A BACKERS' NEEDLE INSTEAD OF FORCEPS, ETC.

PARIS, September 25, 1897.

THE cold weather of the last week has been making itself felt not only by bringing back to Paris members of the faculty and general practitioners as well, but also in an increase in the number of cases of colds, laryngitis and bronchitis, and even pneumonia. Nevertheless, the health *résumé* of the week, according to the *Bulletin Hebdomadaire de Statistique Municipale*, is satisfactory. During the week from the 5th to the 12th of September there were 735 deaths instead of 830, the mean of the September weeks. The zymotic diseases are but little prevalent, causing 8 deaths, to wit: typhoid fever, 4, instead of 11—the average; measles, 1, instead of 7—average; whooping-cough, 2, instead of 5—average; and diphtheria, 1, instead of 10—average. Paris is absolutely free from small-pox, and no one has died in the week referred to of scarlet fever. Although there has been a slight increase in the number of cases of inflammatory diseases of the respiratory organs, it is still below the average; there were 55 deaths from these, instead of 51 as in the preceding week, and instead of 67, the average of the season. On the other hand, there has been a decrease in the number of deaths from pulmonary phthisis—147 instead of 173, the average.

The Academy of Medicine met on the 11th inst., and listened to a very important communication on the dangers of operations on exophthalmic goitre, by Dr. Poncet, professor of the surgical clinic at the Faculty of Medicine of Lyons.

Here is his opinion: "In all cases of true Basedow's disease, try at first internal medications, and continue their use even if the amelioration is slow. In cases belonging to the poorer classes, in those that go rapidly into cachexia or relapse after a momentary amelioration by medical treatment, advise an operation as soon as the functional troubles interfere with the acts of every-day life and before the general condition is too much altered, but warn the patient that there are risks to run.

"If the tumor is of medium volume, remove it by massive enucleation or by partial thyroidectomy. If it is larger and very vascular, give preference to exothyropexia in spite of the perhaps more numerous chances of failure. It will be time enough to have recourse to a secondary excision of the goitre when the partial thrombosis of its vessels caused by exposure to the air shall have diminished the operative difficulties and the chances of intoxication. Some surgeons, among others Kocher and Rydygier more especially, have strongly recommended the ligature of the thyroid arteries as an innocent and efficacious therapeutic measure in the treatment of exophthalmic goitre.

"My own personal experience in the treatment of the different forms of goitre is that the continued current gives by far the best results, and oftenest brings about a complete cure; and I have completely resorbed by its use a simple hyperplasia of the thyroid body as large as a good-sized hen's egg. In the treatment of a case of exophthalmic goitre I reduced the growth by at least one-third. In this case the galvanic current was supplemented by the faradic current. Both were applied as follows: Five minutes on the goitre, by placing the large positive pole on the seventh cervical vertebra and the small negative one on the tumor itself; then five minutes by placing the positive pole with a small tampon below the thyroid body and the negative pole above it; then five minutes with one pole either side of the growth. These applications were followed by five minutes' faradization of the sympathetic—three minutes on the heart and one on each of the eyes, the positive pole always being placed on the seventh cervical vertebra, excepting for the tumor itself and of course the two sympathetics."

A disease about which but little is known beyond the general description in some of the more recent works on the pathology of the nervous system is Thomsen's disease. It is a myotonia, and this is the characteristic of the disease—a special muscular contraction, produced at the beginning of a voluntary movement or change of direction of a given movement, its intensity and duration varying in proportion to the importance of the effort, but remaining absolutely painless. As regards frequency, these motor troubles affect chiefly the lower limbs, more rarely the arms and preferably the hands, then the back of the neck, the face, the body, the pharynx, the tongue, etc. The relaxation of the muscle or muscles affected is more or less slow, according as the effort was greater or less.

I have had quite recently a case of this, in which both the lower limbs were affected. The patient at the beginning of his walk would be suddenly taken with an inability to proceed. His legs refused to move; there was an absence of all pain or numbness, such as we often see in some forms of paralysis. The inability was the only symptom, and this passed off in a few seconds. The muscular contraction was scarcely perceptible, but general—the kind of contraction that takes place in rigor mortis but more rapid, all the groups of muscles seeming to become contracted at once, if contraction there was—a kind of nailing to the ground. This affection, which is often congenital, may also be acquired. Hereditary alcoholism is a productive soil for it. The case referred to was symptomatic—that is, Thomsen's disease was associated with a uric-acid diathesis and rheumatoid arthritis, the patient's nerve centres being irritated and poisoned by uric acid. But as a general rule an organic disease of the nervous system lies at the bottom. Dr. Kornholb, in his thesis, 1897, has thrown considerable light on this obscure affection, and from observations taken in the service of Professor Raymond finds that the principal causes are spinal sclerosis, epilepsy, syphilis, polyneuritis, with muscular atrophy and meningomyelitis.

As regards treatment, that rests entirely upon the *indicatio causalis*. As, however, the circulation is almost always involved, massage, electricity, and douches to the spine are our best remedies. As regards internal medicines, hyoscyamine, arsenic, and Indian hemp may be given with advantage. Personally I find strychnine the most valuable remedy, in doses of one-one-hundred-and-twentieth of a grain twice daily with meals, and continued for three weeks.

Paris is to have another sensational trial. The

court is now taking cognizance of an affair the main features of which are as follows: The wife of a *pâtissier* being in labor, a doctor was called, who, not being able to deliver the woman with a faulty forceps, asked the husband to assist him. The latter brought a box of tools, in which was found a packers' needle. This, it appears, was used to pierce the cranium of the child, which was afterward taken away in pieces. Shortly after the woman was taken with fever and delirium, followed soon by death. Dr. Socquet, the legal medical expert, demonstrated that the woman had died not as a consequence of the delivery, but by the perforations that had been made in different places in the intestines, bladder, and peritoneum.

HYGIENE IN THE BARBER SHOP.

To the Editor of the Medical Record.

Sir: Without trespassing too largely upon your correspondence department, I would like a word bearing upon "Aseptic Barbering," as mentioned by you editorially in the last issue. In my communication to the Medical Record two weeks ago upon "A School for Favus Children," I failed to bring out the point that the majority of the male subjects of favus resort to the barber shop for their hair cutting. During the past five months, out of a total of nearly three thousand skin cases I have seen eighty odd subjects of favus, the great majority of whom I have questioned regarding their habits in this respect, and have found that almost without exception the barber's services are sought and freely received.

The hair is usually cut with the patent clipper. It was only yesterday that a man of twenty-one years, whose disease had existed from childhood, informed me that he went regularly to the barber, who cut his hair without protest, although abundant yellow crusts were present at the time. I always make it a point to instruct such patients in regard to the danger, and tell them to have their hair cutting done at home. Having failed to secure proper co-operation in several instances, I now have the hair of favus patients at the Good Samaritan cut at the institution as part of the routine treatment.

In regard to the relative frequency of the affection in the district in which this institution is located, I may say that in the last report of the American Dermatological Association there are but thirty-five instances given for the year, out of a total of over eleven thousand cases, and the general record from 1887 to 1893 gave for the whole country but three hundred and seventy-three cases out of over ninety-one thousand. It is safe to predict that unless proper steps are taken, the disproportion will not always continue to exist. Charles W. Allen, M.D.

[redacted]

THE PREVALENCE OF TAPEWORM.

[redacted]

Sir: Regarding Dr. E. C. Chamberlin's article on tapeworm in your issue of August 28th, I think his statistics are not borne out by common experience. During my residence of three years in Watertown (population thirty-five hundred), I have had four cases of tapeworm, all in men, ages from twenty-two to thirty-five years; occupations, two butchers, one shoemaker, one railroadman.

My friend, Dr. H. M. Finmond, residing here since 1890, has had six cases, only one of which occurred in a female.

From what I know of physicians in the neighboring towns, their experience is very similar.

George G. Saxe, M.D.

[redacted]

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending October 2, 1897:

	Cases.	Deaths.
Tuberculosis	153	111
Typhoid fever	27	4
Scarlet fever	12	5
Cerebro-spinal meningitis	0	1
Measles	53	1
Diphtheria	131	17
Laryngeal diphtheria (croup)	4	2

Are the Bodily Organs Friends or Enemies?—In answering this question most physiologists would probably say, "Friends; for they act together for the support of the whole organism." M. J. Kunstler takes another view. He tells us that they are enemies, or perhaps rather rivals; for an advantage given to one invariably results in its outstripping the others, to their injury (*Literary Digest*). It is not very long since general biology, he says, in some of its parts, was based on certain theories, mostly philosophical, that ruled supreme over our conceptions of the living organism. Such is without doubt the theoretical view, often advanced, but dating back as far as Aristotle, according to which the different parts of a being form a harmonious whole, in which they all aid each other, in a manner, and complete one another, so that they work together, each in its own way and for the best advantage, to the common good of the whole. An organism would then be comparable to a society wisely constituted of bodies of workers, who labor together in such wise as to protect the whole body from injurious outside influences. This specious and seductive manner of treatment can be refuted only by a somewhat rigorous scientific analysis. Far from giving mutual aid, the different parts of the bodies of living beings seem, on the contrary, to be in perpetual strife with one another. Every development of one of them has for correlative result a diminution of importance in the others. In other words, every part that increases determines the enfeeblement of the other parts.

. . Not only do the organs fight each other, but all other parts do the like, whatever they may be. For example, there is conflict among the tissues, even among the elements of the same tissue. The evolution of the feebler ones is diminished or arrested: they are pitilessly sacrificed to the good of the strong, which thus become more flourishing. Things seem to take place as if living organisms possessed only one determinate amount of evolutive power. If, by means of some artifice, this force of development is taken from an organ or a part, the other organs are more or less completely brought to a standstill, or they may even retrograde. These facts, taken together, lead the mind quite naturally to a comparison with what we see every day in regard to patrimonial succession. In the case in which one of the children of the same family is favored in the partition of the father's estate, the share of the others is by the same fact diminished by that amount. Kunstler has this to say about the effects of exercise: In moderate amounts, exercise has a favorable effect, and facilitates the progress of the organism, while a continual excess of it brings injury. Every degree of exercise cannot be considered of use to the development of the organs that are subjected to it, any more than to the organism as a whole. The well-known example of a certain

fencing-master whose continued professional exercise brought on symptoms of atrophy is a case in point. But without considering extremes, exercise even in relatively moderate amounts can produce undesirable effects, if it is too exclusive and too continued. By a kind of balancing of the organic energy, if one part is specially trained the neighboring organs cease to act, in greater or less degree, and this part becomes relatively preponderant, to the detriment of the others. Besides, it is well known that as a general rule men with powerful muscular and organic development are often not those that present the most intellectual habit of mind. This extreme application of the principle of the balance of organs has even been the object of popular consecration, if we may be allowed to recall the fact that when, in colloquial language, a man is called "fat" or "heavy," it is never taken as evidence of his intelligence. . . . The process that has been indicated has also a general signification and, besides exercise, a multitude of causes can conspire to hasten the development of the bodily elements. All the agents of excitation, such, for example, as alcoholic drinks, physical or intellectual fatigue, grief, all excesses, act thus, and make us "live faster." Trees taken from Europe to Algeria come in a half-dozen years, under the influence of the permanent excitation due to the high temperature of the African climate, to the same stage of development that they would reach in double the time in a temperate region. But then, having used up their whole vital energy, they die. Their leaves have scarcely fallen in autumn when they are replaced by a new growth; they are the seat of an intense life that uses them up quickly. So, also, great workers become weak and feeble before their time. The ephemeral successes of great bicycle racers are striking examples from daily life. M. Kunstler believes that this lack of vitality, due to the abnormal development of one part or faculty, is inheritable, and hence has its effect on the history of the human race. For instance, he points out that city children, compared with those of the country, are more precocious, but have less vitality, owing to maturity hastened by the excitement of city life for generations. He applies his rule also to the cases of certain families or of precocious children in the same family, and finds that everywhere, whether in the individual, the family, or the race, overdevelopment in one part or faculty, instead of helping on the others, invariably retards them.

Ought Physicians to Write Poetry?—A volume of Dr. Frederick Peterson's poems was recently produced in a courtroom where he was giving expert testimony in a murder trial, presumably in order to detract from the value of his testimony. *Leslie's Weekly* makes the following comment: "Whenever a medical man writes poetry it is viewed with some suspicion; the example of Dr. Oliver Wendell Holmes to the contrary notwithstanding. But Dr. Peterson, like Dr. Weir Mitchell, has wooed the muse to some purpose, and his verses are distinctly good. The volume in question was the second he has produced, each of them containing a number of charming lyrics and some clever translations from the Swedish."—*Boston Medical and Surgical Journal.*

The Yukon Fever versus the Medical Fever.—It may be asked by many a young man just now whether he should go to the Yukon or to a medical college. So far as the *Review* is concerned it would not seriously advise either course to glory, a fortune, or the grave. If, however, some youths, ambitious for fortune or fame are determined to go to one or the other of the above places, then really the balance of argument lies in favor of the Yukon. By going to the latter place one will make something soon or lose everything in the attempt. Of two forms of death, it would appear that being frozen is full as easy as the gradual one of starving to death by the slow academical method of attending a medical college. What though fifty per cent. should meet with death by freezing or speedy starvation in the search for gold in the Klondyke, would not the results in the end be better than that ninety per cent. should meet with disappointment in the search for gold after spending many years in the study of medicine? If either form of fever is to attack young men, we think the prognosis is decidedly in favor of the Yukon type, as compared with the medical-school type. The latter is a very lingering disease.—*Canadian Medical Review.*

A Give-Away of the Doctor.—The most curiously decorated graves in the world, perhaps, are the negro graves in Zululand. Some of these mounds are garnished with the bottles of medicine used by the departed in their final illness, and the duration of the malady and skill of the physician are indicated in a measure by the number of bottles.

Duke Carl of Bavaria, the oculist, has performed nearly three thousand operations for cataract. Every one of these operations has been performed between the hours of six and eight in the morning, as the Duke declares his nerves are strongest at this early hour and his hand most steady.

The Plague in China.—A Chinese paper estimates that the victims of the plague in Foochow this year will not fall far short of forty thousand.

Business Improving.—The physicians of Kearney, Neb., recently challenged the lawyers of that place to a friendly game of ball, and the members of the bar hurled the challenge back in their teeth, stating that they were too busy at present settling up the estates left by the doctors' patients.—*Medical Herald.*

Children and Poisonous Flowers and Plants.—Buttercups and daisies are generally associated in one's mind with Wordsworth, children, and Arcadian simplicity. It is difficult to conceive of anything hurtful or dangerous in connection with the pretty little yellow flower, but unfortunately it is not always the most modest and retiring plants or flowers that are the least harmful, for example, the deadly nightshade (Atropa belladonna). Not that the buttercup can vie with the deadly nightshade in poisonous qualities, and still when consumed in sufficient quantities it will cause death. A proof of this has lately been afforded in England in the case of a boy who after eating some buttercups died within a few hours with all the symptoms of irritant poisoning. The buttercup belongs to the ranunculaceæ, and nearly all the members of this group possess poisonous qualities, chiefly of an irritant nature, though in a few narcotic principles are to be found. Every year some children lose their lives by eating poisonous seeds or flowers, and care should be taken to exclude from gardens or parks where children play, plants or shrubs of a poisonous nature, as deadly nightshade, laburnun, and yew. Fortunately buttercups, though nice to look at, do not as a rule tempt children to eat them wholesale, otherwise the mortality from this cause would be much greater than it is at present—*Pediatrics.*

Tears are Good for Woman, says Dr. Campbell, in *The Hospital.* The beneficial effect of a good cry to a woman, he asserts, is partly due to the increased depth of respiration and the improvement in the often languid circulation thereby induced, but to a large extent it is the result of the muscular exercise in

volved, by which the general vascular tension, and especially the blood pressure in the brain, is much reduced. The profuse flow of tears no doubt also acts strongly on the cerebral circulation in still further reducing tension. The sobbing movements, again, have a good influence upon the venous circulation in the abdominal and pelvic viscera, while the exhaustion produced tends to cause sleep, and thus to give the nervous system its best chance of recuperation.

Arterio-Sclerosis.—M. Huchard, in his treatise on diseases of the heart, says that arterio-sclerosis is peculiarly the disease of physicians, politicians, and financiers, their liability to which is largely due to their practising professions in which emotion is often intensified and which involve great liability to overwork. In addition, doctors have to experience unavoidable irregularities in hours and sometimes continuous periods of work without rest. The single means of arresting and avoiding these consequences is by a diminution of anxiety and an avoidance of overwork, with measures taken as far as possible for repair of the wasted tissues.

Bacteriology in Japan.—Nothing in these days is more wonderful than the extraordinary progress made by Japan in almost every branch of civilization. Not only has she modelled her government upon the best civilized examples, drilled and armed her army, and built and armed her navy on the most approved European plans, but she also has taken a high place in scientific and medical research. Her system of medicine has been completely revolutionized, and especially in so far as the bacteriological element is concerned. Dr. Kitasato is probably one of the foremost living bacteriologists, and an interesting account of some of his work is given in *Science* for August 27th, by another Japanese, Dr. Nakagawa, a graduate of Princeton University. To a private citizen, Mr. Fakasawa, the credit is due of building at his own expense a laboratory for Dr. Kitasato and initiating in Japan the teaching of bacteriology. Subsequently the imperial government built and endowed the "Institute for Infectious Diseases," at Tokio, which is under the direction of Dr. Kitasato, and where he conducts his investigations. Perhaps the most instructive part of these researches is that which relates to the "bacillus pestis." In respect to this germ, Dr. Nakagawa says: "The discovery of the plague bacilli is too well known to need mentioning in this connection, were it not for the fact that it seems to be utterly unknown to the world that the bacillus claimed to be the specific germ of the plague by Dr. Yersin is absolutely different from that described by Dr. Kitasato. Dr. Kitasato's bacilli are almost exactly like those of chicken cholera (in shape), *i.e.*, each bacillus presents the appearance of a pair of diplococci, and is, as a rule, considerably smaller than Dr. Yersin's bacillus. Kitasato's bacilli can be stained according to Gram's method, while the other is decolorized by the regular procedure. Kitasato's bacillus is surrounded by a distinct capsule, which is wanting with Yersin's. Moreover, Kitasato's bacilli are motile, but Yersin's are not. There are at present two distinct bacilli held to be the etiological factor of the disease in question. It is to be hoped that the members of the commission sent out to Bombay will help to clear up the confusion." The "Institute for Infectious Diseases" appears to be an establishment complete in all its details, and is fitted up throughout with the latest up-to-date scientific appliances. The library contains most works on infectious diseases, bacteriology, and hygiene, and is supplied with medical periodicals in the English, French, German, Italian, and Japanese languages. The clinical department has beds for fifty patients, and all contagious diseases are admitted, with the exception of cholera and small-pox. It is stated that one hundred and eighty cases of leprosy have been treated in the out-patient department with Kitasato's recently discovered remedy for that disease, in four instances with complete success. A full report of "leprine," the name given to the new remedy, will shortly be published. Japan must be congratulated on the possession of such an institution as the one just briefly described. In bacteriological investigation she has taken the lead of nations far older in civilization and richer in resources.

Fasting and Infection.—The effect of fasting upon the power of the system to resist infection from microbian toxins has been investigated by MM. I. Teissier and L. Guinard, and they find it a strengthening one. Animals which had been kept fasting held out against inoculation much better than the control animals, and the resisting power seemed to increase with the length of the fast.

A Hospital for Consumptives in Paris.—Madame Boucicaut, widow of the founder of the Bon Marché, has left the bulk of her fortune to the Assistance Publique de Paris, a department which supervises the public charitable institutions of the city. Among the sufferers from various diseases who will benefit from this legacy are the consumptives. A building constructed on the most approved system and located in an ideal situation has just been completed. Although the building is large, it contains but one hundred and sixty beds. The treatment will be conducted on the open-air plan, and the greatest attention will be paid to antiseptic principles. This establishment should prove a great boon to the poor of Paris, among whom tuberculosis is common and whose conditions of life are favorable to the contracting of the disease.

Health Reports.—The following statistics concerning yellow fever, small-pox, and plague, have, been received in the office of the United States Marine Hospital service during the week ended October 2, 1897:

YELLOW FEVER—UNITED STATES.

		Cases.	Deaths.
Alabama, Mobile	September 24th to October 1st	40	6
Louisiana, New Orleans	September 25th to October 1st	160	15
Mississippi, Edwards	September 25th to October 1st	126	4
Edwards	September 25th to October 1st	117	3
Mt. Helena	September 25th to October 1st	4	
Ocean Springs	September 25th to October 1st	5	1
Pearlington	September 24th	1	
Scranton	September 26th to 27th	11	

YELLOW FEVER—FOREIGN.

Brazil, Rio de Janeiro	August 21st to 28th		
Cuba, Cardenas	September 4th to 11th		1
Cienfuegos	September 4th to 11th		18
Havana	September 11th to 18th		23
Matanzas	September 8th to 14th		2
U. S. of Colombia, Panama	September 14th to 17th	2	
India, Bombay	August 14th to 31st	193	
Calcutta	August 5th to 21st		6
Madras	August 21st to 28th		7
Singapore	July 1st to 31st		1
Japan, Kanagawa	August 29th to September 2d	1	
Osaka and Hiogo	August 21st to 28th	1	
Tokio	August 24th to September 2d	14	1

PLAGUE—FOREIGN.

India, Bombay	August 17th to 24th		15

SMALL-POX—UNITED STATES.

Birmingham, Ala.	September 18th to 25th	2	

SMALL-POX—FOREIGN.

A PLEA FOR THERAPEUTIC CONSERVATISM.[1]

BY SETH A. MERENESS, M.D.,

CARLISLE, N. Y.

THE extraordinary progress made in certain departments of medical science during the present century, and especially its latter half, sometimes makes it appear as if the physician has at last reached *terra firma* in the treatment of disease. In histology and physiology, pathology and diagnosis, and in surgery and bacteriology the progress has certainly been great and most satisfactory.

Physiological chemistry and experimental pharmacology have also made rapid strides and the physiological action of many substances used in the treatment of disease is now definitely known.

But in spite of all this advancement of our knowledge of the human economy in health and disease, and of the materials used to allay suffering or bring about a restoration to the normal, it is not certain that we are better able to combat individual disease with pharmaceutical remedies than were the physicians of two and indeed twenty centuries ago.

The average duration of life is undoubtedly longer now than formerly, but when the prevention of infectious and often malignant diseases by vaccination or hygienic measures is taken into account, together with the better general knowledge of how to live and avoid disease, it is very probable that were it not for these conditions human mortality would be as great, if not greater, now than in times past.

Ever since the beginning of the Christian era and even long before, if we may credit our medical historians, there has been a continual change in medical theory and practice.[2] Methods which are deemed well-nigh infallible in one generation are supplanted by others in the next, and by the third generation the old method is mentioned as being not only unscientific and useless, but exceedingly injurious. Sometimes after a period of obscurity an old method is again taken up and lauded, to be soon criticised, condemned, and retired. One has only to read over the list of the various therapeutic sects to be made sceptical. If therapeutics rests on a scientific foundation, why this endless array of contradictions? We have only one scientific anatomy and physiology, one chemistry, and one bacteriology; why then a dozen or more sects in theoretical and practical therapeutics? Obviously, its theories and their application rest on insecure scientific foundations. By this it is not intended to discredit the really scientific knowledge of the physiological action of pharmaceutical or natural compounds on the animal economy, but only the utility of the administration of such in many pathological conditions.

The almost universal acceptance of cellular pathology as established and persistently advocated by Virchow[1] and others, in the middle of the present century, opened a new field of inquiry and has been the means of explaining satisfactorily many of the phenomena of vital organization.

Before this the fundamental anatomical processes of organic growth, tissue destruction and repair, or degeneration and regeneration, were explained by the most diverse hypotheses, many of which were more remarkable for their dogmatic incongruities than for their scientific explanations.

But that attribute or essence of living organisms which distinguishes them from inorganic substances is not more definitely known now than in times past. It still remains the sphinx of biology, and the cellular pathology no more explains the nature of the fundamental vital principle than did the ancient humoral, and its bitter antagonist, solidar pathology, or the iatro-mechanical theory of more recent times.

During all the centuries of which we have a record of medical science there has been the belief that there was a specific something which distinguished living from dead material; which caused, under certain conditions, organic substances to live, grow, and reproduce themselves; and a deterioration or loss of which brought about changes and eventually a return to inorganic compounds. Of these material changes cellular pathology has taught us much; but of the primitive causes of the changes almost nothing.

The ultimate analysis of natural phenomena leads to the acceptance of two primary factors, viz., matter and motion, and as a hypothesis it has been assumed that from the interaction of these the various kinds of matter and manifestations of force have been caused.

The application of force to matter may change the latter, as is shown by subjecting various substances to the action of heat, light, or electricity, whence changes in volume and in consistency, and even new chemical combinations, occur.

Again, daily experiences in mechanics and the arts demonstrate the convertibility of one force into some other. Mechanical motion may be converted into heat or electricity and *vice versa*, while heat and electricity may be converted into light and chemical action. From this it may be considered that mechanical force, heat, electricity, light, and chemism are, as Tyndal[2] expresses it, but modes of motion and may be transformed the one into another. According to this view, the rapidity and amplitude of molecular motion determine the varieties of force which are only to be differentiated by the phenomena resulting from their action on matter.

The changes which in this way lead to varieties of structure are still material and inorganic. That is, they do not present the characteristic biological phenomena common to living organisms. Indeed all the known kinds of matter and the varieties of physical force may be present, but the selective ability of liv-

ing organisms to maintain themselves for a definite time, to transform spontaneously one motion into another, and then to perpetuate themselves is wanting. Here is the necessary missing link between inorganic and living organic phenomena. Is this missing link matter or motion? If material, what is it? And if force, how does it differ from the other modes of motion, and can it be transformed into the others or *vice versa*?

These are questions the answers to which underlie the whole groundwork of biological and consequently medical science, and until they are definitely and correctly answered exact knowledge of organic phenomena cannot obtain.

That this missing link is not matter seems to be demonstrated by the capability of living organisms to maintain themselves, increase in volume, and perform their functions by transforming inorganic materials; and when because of natural limitation or on account of environment the living functions cease, organic substances become changed into inorganic. Besides, to consider vital phenomena as being caused by a specific material substance necessitates the hypothesis that either a material substance can cease to exist, or can continue to exist without its characteristic attributes, either of which the law of persistence of matter and its attributes disposes of at once.

Excluding a material substance as the cause of vitality, there are but two alternatives: either to believe the cause to be immaterial and supranatural, or to admit a primitive or modified specific force. The first, while possible, has nothing but belief to defend it, and can never be expected to be proven or disproven on scientific grounds. The second explains much and is supported by analogies if by nothing more.

How the first vital phenomena occurred is not, probably never will be, known, but once grant its occurrence and the way for hypotheses is clear.

Scientists tell us that the vegetal cell through the agency of solar force assimilates inorganic matter and transforms it into organic, and that, too, without change, other than molecular, of the elementary materials. The inorganic elements, oxygen, nitrogen, carbon, or whatever they may be, remain the same in the living structure as in the inorganic, only their relations to each other change, either as to quantity or the relative position of their molecules. During this transformation a portion of the solar force is stored up in the organic substances, which is again liberated when the cell is destroyed or undergoes retrogressive changes.

Aside from the peculiar property possessed by a living cell to assume automatically a definite structure and to transmit this capability to its offspring, there is very little in vital phenomena which does not appear to be governed by the laws of inorganic nature.

But this property is now, as it has been for centuries, so characteristic and inexplicable that it has been accepted as a distinct entity and designated by various names, of which vitality and vital force are representative. It has never been demonstrated, however, that vital force is primitive or specific, and its acceptance as such is purely hypothetical. Indeed, there is much to justify the belief that vital force, if there is really such, is simply another mode of motion, capable of being transformed into other forces but never destroyed, and able to alter the properties but not the essence of inorganic elementary substances.

Perhaps the future may show that what we call vitality is neither specific matter nor force, but the resultant of the interaction of both, under certain conditions now entirely unknown.

What we do know, however, is that this vitality, be it what it may, is a [illegible] for the assimilation of inorganic materials, the maintenance of life, and the occurrence of reproduction.

One of the great merits of the cellular pathology is that it necessitated a careful, scientific examination of what is now accepted as the foundation of organic structures, viz., the cell. Whether with or without a membrane the essential material is its protoplasm, which, according to Huxley,[1] may be considered as a type of all primitive living substance.

This almost homogeneous organic compound has above all other characteristics one in particular, and that is instability. Being of a most complex structure, not only from its containing several elements but from its multiple molecular combinations, it is not at all strange that the compound is so unstable. Moreover, when it is considered that in chemical unions the rearrangement of even one molecular group produces a substance with entirely different characteristics, it is easy to conceive that even an elementary organism may present millions of changes, and while all the time retaining a typical structure the individual is never twice alike during its existence.

Herbert Spencer[2] maintains that the higher the organization of matter the more unstable the resulting substance becomes, since there is always a tendency to equilibration. In living organic substances the vital principle strives to bring the organic unit to a definite structure and maintain it, while the environment constantly endeavors to reduce it to a more simple structure, even to its primitive inorganic constituents.

To remain in a condition in which the protoplasmic mass can perform its functions normally—that is, in health—is the constant automatic aim of every biological unit, otherwise an enduring condition of vitality would be impossible. In order that an organic unit may preserve its vitality and perform its functions, force must be constantly expended. The assimilated material with its stored-up solar energy is of service only so long as the reorganization of its molecules develops force.

The principal physical function of an elementary organism is to decompose various substances and to change potential into kinetic energy, or *vice versa*, and this decomposition produces various modifications of motion, as heat, chemical action, and changes in polarity for the lower organisms, while in the higher, in addition to these, there is developed muscular contractility and perhaps even cerebration. When protoplasm can no longer make use of its potential or has used what is available, its own molecular structure probably changes to a more elementary condition in order to evolve more force, resist external and internal harmful influences, and to maintain a suitable temperature. This phenomenon continues until the living protoplasm loses its essential characteristics and is no longer capable of producing vital phenomena, in other words the protoplasm is dead.

Vitality is then only a relative term and expresses the degree of organization necessary to life, which is probably not the same for all living material. Hence molecular complexity varies, and, while its falling below a certain grade causes impairment of function and death, its development is limited only by the original vital intensity and the possibilities which the environment allows.

Health and disease are also only relative terms, the one signifying the condition of an organism when it is able to maintain a degree of organization necessary to produce normal functions, and the other expresses the condition when organization and consequently function are below the normal. The dividing line, if there is one, is entirely unknown for the lower organisms. For complex organisms, however, the disturbance of a collective function may very properly be termed dis-

[1] "The Physical Basis of Life," London, 1868.
[2] "Principles of Biology," vol. i., London, 1864.

ease, although the constituent cells of the organ causing the function are in various conditions, some normal, others living but feeble, while others are *hors de combat*.

The most characteristic physical phenomena of living protoplasm is its reaction to external antagonistic influences. This presents itself to our senses by certain movements, contractility, and the general property of protoplasm to recognize injurious contacts is termed irritability; and this irritability is the most apparent and reliable index we have of cellular vitality.

From its physical manifestations it is possible to learn in a restricted sense the behavior of a cell in its environment and to note the effect of the latter on its vital phenomena. According to Engelmann[1] the application of force from without under certain conditions constantly causes the irritability of living protoplasm to manifest itself; whether the force be mechanical motion, heat, electricity, light, or chemical action, the result appears to be the same except as to intensity. When very feeble force is applied the reaction is so mild that it cannot always be recognized, but we are not to suppose from this that no molecular changes have taken place. When a sufficiently strong force is applied protoplasm quickly manifests its irritability by contracting, which in itself must demand a liberation of energy, and molecular changes probably succeed each other more rapidly than under normal conditions.

The length of time for which protoplasm continues to manifest its irritability depends on the intensity of the irritant and the amount of potential possessed by the cell. Contractility ceases at once under intense stimulus, but may appear again after a variable time if the irritation is not too intense or too long applied. Under moderate irritation the power of contracting remains for a relatively longer time and finally is lost, but is regained after a period of rest.

Very strong stimuli seem to arrest the movements of protoplasm at once, evidently because of the molecular changes induced by the irritant directly and not indirectly by the organism in defence of its existence. Certain substances without any apparent manifestation of force also cause the phenomena of protoplasmic irritability to appear, and this is notable of the irritant poisons. Their application causes at first increase of motion and later paralysis. The duration and extent of the one, as well as the time necessary to produce the other, are determined by the concentration of the poison and its specific power of producing vital reaction. The explanation of the action of irritant poisons is not so satisfactory as that of the application of force. Since, however, living protoplasm normally requires a nearly neutral environment, it is quite obvious that certain inorganic poisons, such as the mineral acids and the alkalies, owe their harmful action to the property of rendering the surrounding media either acid or alkaline.

Other poisons and especially the alkaloids are, as Kühne[2] showed many years since of veratrum, able to produce a very intense irritation, even when applied in neutral solution. But these poisonous alkaloids are highly complex organic compounds, and for this reason may have a specific action which easily disintegrates the molecular combinations of the more highly organized protoplasm. Again, it may be believed that the more complex the molecular arrangement the higher the function produced. For this reason the protoplasm of the highest order would be utilized in carrying on the nervous function. When from the presence of poisons like the acro-narcotics the arrangement of the molecular groups is simplified and the cells are no longer capable of continuing their highly specialized nervous function, it is still possible for the cells to retain their vitality and continue their nutritive functions.

From the facts recorded by many painstaking investigators of physiological and pathological cellular phenomena, notably Ch. Robin,[1] Ziegler,[2] and O. Hertwig,[3] it may be said in general that the application of any of the various forces as well as certain poisonous materials agree in so far as they all cause at first acceleration of protoplasmic movements, then inhibition, and finally paralysis. The cell increases in size, its contents become clouded and opaque, and its functions are at first impaired, later destroyed. In fact these conditions are very similar to those that obtain in acute inflammatory processes, especially of the spinal cord when the neural cells are undergoing a process of acute degeneration.

There would be no life were it not for the automatic capability of an organism so to arrange its structure as best to antagonize harmful influences of its surroundings. The observations of Darwin[4] alone, which, however, have been supplemented by scores of other scientists, leave no doubt as to the variation of type which follows a modification of environment. Not only do plants and the higher animals become changed, but also the lower orders.

Thus Maupas[5] has shown that certain salt-water infusoria when removed to fresh water died at once. However, when the change was made gradually, the organism not only lived but lost entirely its salt-water characteristics and became like the analogous fresh-water varieties. When the animal was returned to salt water its former characteristics returned. Here is seen an attempt, and a successful one, of a living organism so to change its structure as to be able not only to resist external influences, but also to assimilate material which it had been unused to and thus maintain itself in its new surroundings.

This selective capability of vital maintenance in the sense of causing recovery from disease has been believed and maintained from comparatively ancient times and constitutes the much used but sometimes little heeded *vis medicatrix naturæ*. That the human economy possesses the power of resisting influences antagonistic to life, and is able when these influences are not too harmful or long continued to perform its normal functions, is certainly not to be doubted, even if the cause and *rationale* of the phenomena are but imperfectly or not at all known.

Can these harmful influences be modified or neutralized by means that are under human control? Or can the living protoplasm be aided in its resistance to destructive environing forces? If the answer to either or both is in the affirmative, then therapeutic measures are of service; if in the negative, they will have no practical value except that of causing a temporary relief from disagreeable symptoms.

Certainly the application of hygienic measures securing satisfactory nourishment and assisting the economy in excreting poisonous materials has been of inestimable service, and without doubt has been the means of restoring to health or prolonging the life of myriads. A criticism of these measures, when their

application is judiciously accomplished, would be a most thankless task.

But can the administration of substances, many of which are never normally present in the economy, aid the natural processes in their struggle to overcome disease? Perhaps nearly all physicians would answer this in the affirmative, and yet not a few of the more conservative would impose restrictions—in the affirmative because theoretically at least it would seem possible to supply the cellular structure with materials the absence or deficiency of which prevented the necessary normal metabolic changes; and with restrictions because many of the commonly used pharmaceutical compounds are irritant poisons, the beneficial action of which is still problematical.

Of those substances which *a priori* might be expected to increase the efficiency of cellular metabolism a number are prominent, viz., iron, calcium, phosphorus, potassium, magnesium, and sulphur, mostly in combination with oxygen or as substitute compounds in the various acids. All of these elements are normally present and are necessary to organic tissues. The amount of most of these necessary mineral substances is comparatively small, and, since the vegetal process has already combined them and stored them in or around the cell, it is a question whether they may be of service except when the food is deficient in these elements.

Again the various ferments as found in the gastric, hepatic, and intestinal secretions, which are necessary to change the food into cell pabulum, may be furnished in too small quantities or be of impaired quality. Under such conditions the administration of these ferments, as elaborated by normal organs, should be of service. Also to prevent the accumulation of certain unknown toxic substances the administration of the various internal secretions of certain glands, as the thyroid and suprarenals, seems to be indicated.

All of these measures under proper circumstances are no doubt of the utmost importance to the diseased organism. Experimentally, physiologically, and empirically they have, according to our most competent investigators, caused a restoration to health sooner than would have obtained without them, or have brought about a normal condition when it could not have been expected from the *vis medicatrix naturæ* under hygienic and nutritive measures alone.

These therapeutic measures, however, constitute only a part, and in acute diseases a very small part of those usually recommended, and are generally used to restore the tissues to their normal nutritive states or functional activity rather than to combat individual symptoms.

In the acute diseases, which for the most part, thanks to bacteriology, are now universally believed to be due to living organisms, the administration of remedies has quite a different object in view, and it is in this domain of therapeutics that the writer would plead for more conservatism in the use of pharmaceutical remedies.

The treatment of many acute diseases, notably the specific pulmonary and enteric inflammations and the exanthemata, with many physicians resolves itself into combating symptoms which are unpleasant to the patient or are considered dangerous to the economy. To subdue pain, reduce the temperature, and inhibit or paralyze cardiac action are the main ends sought through the use of drugs; and it might seem on superficial inquiry that, since various symptoms are not present in the healthy human subject, all that is necessary is to cause their disappearance and you have the patient in a condition of health. But from a standpoint of empiricism, as well as experimentally, it is known that the removal of symptoms does not at all constitute a *restitutio ad integrum*. In fact pain, pyrexia, and increased pulse rate are universally known to be only a result of disease and not a cause. When certain living organisms, such as bacteria, remain long in contact with the tissues a reaction occurs, just the same as when a force is applied. Whether the growth of these cellular organisms would alone cause this reaction is not known, since it is impossible to isolate living bacteria from their poisonous excretions for any considerable length of time. However, those which do not elaborate toxic substances may remain long in the tissues without causing manifestations of irritability, although their growth may affect the tissues by withdrawing nourishment.

Bacteria cause disease then directly by disturbing nutrition, true parasitism, and indirectly by toxins which they produce. Thus, true parasitism tends to weaken cellular vitality by withdrawing necessary nutrient materials, while the poisons elaborated irritate the protoplasm, causing increased molecular changes and a more or less rapidly progressive degeneration.

If the pathogenic bacteria were able to develop continually there could be but one termination of all infectious diseases, and that a fatal one. However, as has been stated, when living organisms liberate force to antagonize untoward influences, changes take place which simplify or reduce the molecular structure of protoplasm, and thus it happens that there is formed at last an end product which is still nitrogenous and of complex structure, but not sufficiently so to carry on vital functions. Wherever there is life there will be found as a necessary accompaniment these end products, which not only are of no further use but act as an irritant poison on the economy which produced them. Thus there are produced in the animal economy urea and allied compounds, while the vegetal cellular process gives as end products many nitrogenous substances, some of which are highly poisonous, as the various alkaloids, while living bacteria produce substances which are not yet well known but which are nitrogenous and chemically similar to the crystalloids and colloids produced by animal and vegetal organisms.

Fortunately the living cell is able to excrete these poisonous products and thus free itself from their deleterious action, and this happens in all living organisms but in various ways; for, while animals have a definite excretory apparatus, plants have not, and because of this the poisonous products of vegetal metabolism can be excreted by the cell but cannot be further disposed of except by storing them where they cannot come in contact with the living protoplasm. Many end products from urea of the animal tissues are not only chemically analogous to strychnine, morphine, and other alkaloids and to the bacterial toxins, but have in many instances a similar physiological action. Again, these poisons not only produce characteristic phenomena when administered to an animal but affect all living organisms to a greater or less extent. As is well known, the poisonous alkaloids are not only capable of destroying animal life but are able to destroy the vitality of the plant which originated them, and, as Marcacci[1] has shown, are especially harmful to the developing plant. Urea and allied substances are toxic to the human economy and also to the vegetal when applied in a concentrated solution, as every well-informed agriculturist knows, while the poisonous action of certain vegetable alkaloids as well as bacterial toxins on the animal organism is beyond dispute.

The reaction of the animal economy to these various poisons differs according to the nature of the animal and its environment, the quantity and concentration of the poisons, and finally its specific nature.

[1] "L'azione degli alcaloidi nel regno vegetale e animale." Annali di Chim. ed di Farmacol., 1887, p. 3 *et seq.*

But in general tissue metabolism, body temperature, and blood circulation are increased, while muscular and nervous energy is decreased.

While it is not impossible that the increased tissue metabolism is the principal if not the sole cause of the other phenomena, it can be exactly determined only by quantitive estimation of the products of retrograde tissue changes, which under the various means of excretion and the difficulty of collecting the products is almost impossible. And even more difficult is the precise quantitative determination of the nutritive states and the dissipation of energy.

The physician, then, as a general index of the intensity of the morbid process, relies on various symptoms, of which pain as the psychical expression of protoplasmic irritation, fever the result of increased heat production or diminished radiation, and abnormal cardiac action from irritation of the cardiac motor ganglia or the vasomotor nervous system, as well as the disturbed inhibitory action of the pneumogastric, are the most conspicuous.

Very often indeed the combating of these symptoms seems to be the sole aim of pharmacological therapeusis, and it must be admitted that not infrequently the object is accomplished.

Thus the administration in physiological doses of the vegetable narcotics, opium, hyoscyamus, and cannabis indica, certainly can very often prevent the patient from being conscious of pain; aconite, veratrum, digitalis, and many others reduce the pulse rate; while kairine, thalline, and quinine, as well as many modern phenol derivatives certainly reduce the body temperature. But is it not to be questioned whether all these really assist the economy in its struggle with disease? And may not the very physiological or pathological action which causes the improvement in or removal of the symptoms be inimical to normal vital functions?

An infectious disease may be recovered from only through limitation of the growth of bacteria which produce it. Two factors may serve to accomplish this. First bacteria can live and remain normal only in suitable culture media, and since the peculiar pabulum necessary to nourish them is limited in quantity it occurs that when this is exhausted nutrition is impossible, and development and vitality cease. In the second place the poisons excreted by the bacteria serve to restrict their growth and destroy them. It is not known to what extent each of these factors contributes toward recovery. But theoretically it would seem that the first means is alone to be trusted, since the animal economy may be able to dispense with a part of its organic material which contributed to the nourishment of the parasite without much permanent harm, while the second factor may not only kill the bacteria but the patient, as the results of a famous modern toxin remedy seem conclusively to have shown.

Life has often been maintained for years under the most excruciating pain without apparent physical deterioration, as cases of neuralgias and other chronic nervous diseases testify.

Again, there are those who without apparent disability have a high pulse rate during their entire life, while cases of tachycardia are occasionally met with in which a pulse rate of 140–200 per minute for several days or weeks not only does not cause death but does not seem to disturb very much the patient's general health except as to nervous phenomena.

In the same way a moderate rise of temperature, according to Cantani,[1] has been endured for months without death, and healthy animals have been subjected to a temperature considerably higher than normal for months without causing untoward results, as has been shown by Naunyn.[1]

Also the observations of Tait,[2] Bryant,[3] Unverricht,[4] and many others, show that often patients with a temperature as high as 43° or 44° (109°–111° F.) have been met with and have recovered.

These facts serve only to show that these various symptoms may exist for a long time and be very severe without a fatal result, and that too often when but little medicine was administered.

Again, every physician is familiar with the fact that the danger to life is not at all proportionate to the severity of the symptoms. It is not the pneumonias with the highest fever and very severe pains that are most fatal, as the mortality from this disease in the aged, with whom all the symptoms are usually mild, shows, or the infectious processes with the highest temperature and pulse rate, as pyæmia and certain mixed infections testify.

It has never been demonstrated that combating symptoms ever of itself has caused a cure, in the sense of complete restoration to the normal, or has even assisted the natural forces, since there are no statistics, at least none that the writer has knowledge of, covering a long period and including a large number of cases in which acute diseases have been treated by hygienic measures alone. Certainly a large proportion of patients, in fact a majority, recover after the administration, even in considerable quantities, of poisonous drugs, but whether because of their action or in spite of it has never been proven. And it is not less certain that in many even grave cases recovery ensues without the use of pharmaceutical remedies, as the recoveries in many hydropathic and hygienic institutions show.

Our text-books and teachers of therapeutics are mainly responsible for the propagation of symptomatic medication. The student is often informed that when a patient presents such and such symptoms an active attempt should be made at once to remove them. "Administer aconite, gelsemium, and morphine," says one. "This will bring about relief from pain, a reduction of the pulse rate, and lowering of temperature." "But," says another, "I get better results from veratrum, hyoscyamus, and belladonna." After these remedies have been diligently administered, perhaps recovery has not taken place, but the rise in temperature and other symptoms have become still more serious. "Now choose among a dozen, antipyrin, acetanilid, thallin, or kairin, according to circumstances; and perhaps very large doses of quinine will be more efficacious and less harmful." After a time in consequence of the disease, perhaps aided by drugs, the heart action becomes very weak and rapid. "Now is the time to administer digitalis, strophanthus, caffeine, strychnine, and alcoholic stimulants," says the therapeutist, "if you hope for recovery." And yet in spite of all this the patient does not recover. "Well, you accomplished all that was possible in the present state of our knowledge," he continues, and proceeds with other symptomatic indications and the drugs necessary to annihilate them.

When recovery takes place the novice has, or thinks he has, *prima-facie* evidence that the various drugs caused a cure, and so continues perhaps from day to day to attribute all recoveries to his narcotics, antipyretics, cardiac depressants, stimulants, *et id genus*

omne; and when a fatal result follows their use believes that it might have been because a wrong selection was made, or that no system of treatment would have been of service.

The science of pharmacological therapeutics, as applied to acute diseases, is very often expounded in an oracular manner and, now as for centuries past, rests on almost no other foundation than empiricism and pure dogma. *Contraria contrariibus curantur*, one of the oldest and most universally accepted of these dogmas, has certainly been a sheet anchor. But even this cannot be true for diseases which are caused by micro-organisms, if the real cause is considered, since the various alkaloidal remedies used are similar to the toxins in almost every particular. Moreover the supposed physiological antagonism between certain alkaloids has received but scant support in the last few years, and even if true cannot aid in making an exact therapeusis until the specific action of the various toxins has been determined and substances can be found which will not antagonize the symptoms produced by the toxin, but will destroy its harmful influence on the vital units.

The discovery of phagocytosis and of means whereby it may be artificially produced, and the results of recent serum therapy, have invigorated the old doctrine of the *vis medicatrix naturæ;* while experiments on the living animal are showing more and more clearly not only the inadequacy of symptomatic therapeusis to bring about a restoration to the normal, but also the possible dangers which can be caused by the administration of poisonous alkaloids and the recently discovered antipyretics.

Authorities such as Binz,[1] Rossbach,[2] and Rosenthal [3] have shown conclusively that protoplasm cannot produce normal manifestations of energy when acted on by the poisonous alkaloids. And others, as Robin,[4] Kast,[5] and many more, have found that the normal tissue metabolism cannot continue under the influence of various modern antipyretics.

Perhaps the time will come when our text-books on therapeutics will devote most of their space to the consideration of causal and not symptomatic indications, and therapeutic specialists will be unnecessary. When the student learns from his pharmacology the doses, physiological action, and manner of elimination of drugs, and from biology the exact nature of organs and functions, he will no longer need a dogmatic opinion as to the indications for the administration of drugs. Then, too, he may be taught to look at disease from a causal point of view, and learn that it requires more scientific attainment to know when not to administer a drug than it does to treat symptoms. And long before this takes place let it be hoped that the therapeutic *vade mecum* in which the student has only to look in the index for the name of a disease and on referring to it find from one to ten poisonous drugs indicated as a regular treatment, will have become a thing of the past. Drugs without doubt have been of very great benefit to mankind and will continue to be more and more of real service, but it should be remembered that they are able to cause harm as well as good; that the indications for their use, especially in acute infectious diseases, rest for the most part on unproven dogmas: and that when the indications for the use of a drug are doubtful or wanting, it had better be withheld. In all cases the antagonism between living material and irritating surroundings should be borne in mind, and an attempt made to keep the cellular vitality and energy at its most efficient point by supplying proper materials for nourishment, pure air, and water, to assist the chemico-vital processes, and finally to assist the excretory organs in the removal of the poisonous products of animal and vegetal cellular metabolism. And in the mean time the ancient meaningless *contraria contrariibus curantur*, as well as its more modern fanciful opposite, *similia similibus curantur*, will receive due honors if they are laid away with other famous mediæval curiosities, such as the problem of circular quadratics and the philosopher's stone.

THE EARS OF GRASSHOPPERS, FLIES, AND BEETLES.

BY JAMES WEIR, JR., M.D.,

By far the larger number of entomologists locate the auditory organs of insects in their antennæ. I have only to mention the names of such men as Kirby, Spence, Burmeister, Hicks, Wolff, Newport, Oken, Strauss, Durkheim, and Carus, who advance this opinion, to show what a formidable array of talent maintains it. Yet my observations lead me to believe otherwise, though these authorities are in part correct.

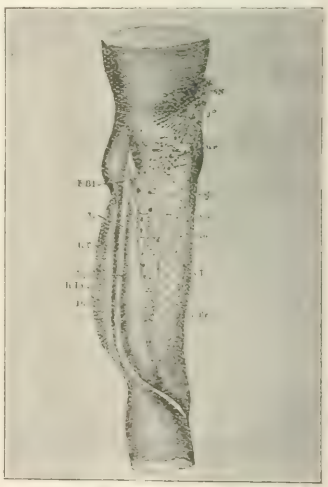

FIG. 1. [illegible]

As far as Lepidoptera are concerned and certain of Hemiptera, they are right—the antennæ in these creatures are the seat of the organs of audition. But in Orthoptera, in most of Coleoptera, in Hymenoptera, in Diptera, and in certain bugs (Hemiptera), they are located elsewhere. The habit that almost all insects have of retracting their antennæ when alarmed by noise or otherwise has done much to advance and strengthen the opinion that these appendages are the seat of insect ears; yet I am confident that in nine cases out of ten the antennæ are retracted through fear of injury to them, and not through any impression made on them by sound. The antennæ are the most exposed and least protected of any of the appendages

or members of the insect body; hence their retraction by insects when alarmed is an instinctively protective action. They shelter them as much as possible in order to keep them from being injured. Again, although the antennæ of most insects are provided with numerous sensitive hairs or setæ, we have no right to assume that these hairs are auditory; no "auditory rods," otoliths, etc., are to be found generally in antennæ, yet there are exceptional instances. Leydig found auditory rods in the antennæ of *Dytiscus marginalis* (Furneaux) (giant water beetle), and I myself have observed them in Corydalus cornutus (its larva is the well-known "dobson" of anglers) and other neuropterous insects. I am inclined to believe that the entire order of Neuroptera has antennal ears, and should therefore in this respect be classed with Lepidoptera.

FIG. 2.—Ear of Horsefly (after Lowne, modified by the author)

In grasshoppers and crickets the ears are situated in the anterior pairs of legs. If the tibia of a grasshopper's anterior leg be examined, two (one before and one behind) shining, oval, membranous discs, surrounded by a marginal ridge, will be at once observed. These are the tympana or ear drums of the ear of that leg. Where the trachea or air tube enters the tibia it becomes enlarged and divides into two channels; these two channels unite again lower down in the shaft of the tibia. The tracheæ of non-stridulating grylli are much smaller than those of sound-producing grasshoppers. The same may be said of the tibial air tubes of the so-called dumb crickets. In grasshoppers and crickets the ear drums lie bathed in air on both sides—the open air on the external side and the air of the air tube or trachea on the inside. Lubbock calls attention to the fact that "the trachea acts like the Eustachian tube in our own ear; it maintains an equilibrium of pressure on each side of the tympanum, and enables it freely to transmit atmospheric vibrations."

In grasshoppers the auditory nerve, after entering the tibia, divides into two branches, one forming the supratympanal ganglion, the other descending to the tympanum and forming a ganglion known as Siebold's organ. This last-mentioned ganglion is strikingly like the organ of Corti in our own ear, and undoubtedly serves a like purpose in the phenomenon of audition. The organ of Corti is composed of some four thousand delicate vesicles, graduated in size, each one of which vibrates in unison with some particular number of sound vibrations. The organ of Siebold in the grasshopper's ear begins with vesicles, of which a few of the first are nearly equal in size; these vesicles then regularly diminish in size to the end of the series. Each of these vesicles contains an auditory rod, and is in communication with the auditory nerve through a delicate nerve fibril. I have observed that each of these nerve fibrils swells into a minute ganglion immediately after leaving its particular vesicle; the function of these ganglia is, I take it, to strengthen and reinforce nerve energy. No other observer mentions these ganglia, as far as I have been able to determine; they may have been absent, however, in the specimens studied by others, yet in the specimens studied by myself—the "red-legged locust" (*Melanoplus femur-rubrum*, Comstock) and the "meadow grasshopper" (Xiphidium)—they were always present.

That grasshoppers, locusts, and crickets can hear, no one who has observed these creatures during the mating-season will for one instant deny; they hear readily and well, for in most of them the sense of hearing is remarkably acute.

Immediately behind the wings of flies two curious knobbed organs are to be observed; these are considered to be rudimentary hinder wings by entomologists, and are called the halteres. Bolles Lee and others of the French scientists call them *les balanciers*. This latter name I consider the correct one, for these organs unquestionably preside over alate equilibrium; they are true balancers. I do not propose to enter into any discussion as to whether these organs are rudimentary wings or not; suffice it to say that they appear to me to be organs fully developed and amply sufficient to serve the purposes for which they were created. Whether or not, in the process of evolution, there has occurred a change of function, is a point which will not be discussed in this paper. As they now exist, I deem them to be the auditory organs of Diptera (flies, gnats, etc.).

The semicircular canals are, to a great extent if not entirely, the seat of equilibration in man. Any derangement or disease of these canals interferes with equilibration; this is well shown in Ménière's disease, in which there is always marked disturbance of the equilibrating function.

If the balancers of a horsefly (*Tabanus atratus*, Comstock) be removed, the insect at once loses its equilibrium; it cannot direct its flight, but plunges headlong to the ground. The same can be said of Chrysops niger—in fact, of the entire family of Tabanidæ, of the gall gnat (*Diplosis resinicola*, Comstock), and of the March flies (Bibionidæ). These widely differing flies constitute the material from which I have derived my data; I will venture to assert, however, without fear of contradiction, that what has been said about the flies mentioned above is equally true of all flies.

FIG. 3. Head of Gnat, showing Auditory Hairs (after Johnson).

When the knobbed ends of the balancers of the horsefly (*Tabanus atratus*, Comstock) are examined with the microscope, the cuticle will be found to be set with minute hairs or setæ; some of these hairs penetrate both cuticle and hypoderm, are hollow, and receive into their hollows delicate nerve fibrils. These nerve fibrils pass inward toward the centre, and enter ganglia, which in turn are in immediate connection with the great nerves of the balancers. There is but one nerve in the insect's body that is larger than the balancer nerve, and that is the optic nerve; hence it is

natural to infer that the balancer nerve leads to some special-sense centre. This centre, in my opinion, is unquestionably the seat of the auditory function. It has been demonstrated beyond doubt that analogous hollow hairs or setæ are prominent factors of audition in many animals, notably crustaceans, such as the lobster, the crab and the crayfish, and many of the insect family; hence it is logically correct to conclude that the hollow hairs on the balancers of flies are likewise auditory hairs. Moreover, there are grouped about the bases of these knobbed organs certain rows of vesicles, which contain auditory rods almost identical in appearance with the auditory rods of the grasshopper. I have determined that in the horsefly (*Tabanus atratus*) there are six rows of these vesicles, and that they are of graduated sizes. There are in the knobs of the balancers minute spiracles, through which air passes into the large vesicular cells which make up the greater portion of the knobs; spiracles are also to be found in the shafts of the balancers, thus providing an abundance of air to the internal structures of these organs and allowing for the free transmission of sound vibrations. I am well aware of the fact that in considering these organs to be the ears of flies I antagonize Lee, Hicks, Wolff, and others who consider them olfactory in character; but from their position, their structure, and, above all, the markedly evident part they play in alate equilibrium, I think the position I take in regard to these organs is a tenable one and one that cannot easily be overthrown.

The ears of Lepidoptera (butterflies) are situated in their antennæ. This fact has been cleverly demonstrated by Lubbock, Graber, Leydig, and Wolff; but in Coleoptera (beetles) my experiments and microscopical researches compel me to assert that I differ somewhat from the conclusions of the above-mentioned authorities. These gentlemen locate the ears of beetles in their antennæ. Lubbock bases his conclusion on an experiment of Will—an experiment which, if it had been carried a little further, would have demonstrated the fact that the ears of beetles are not in their antennæ, but are, on the contrary, in their maxillary palpi.

Will put a female Cerambyx beetle in a box, which he placed on a table; he then put a male Cerambyx on the table, some four inches from the box. When he touched the female she began to chirrup, whereupon the male turned his antennæ toward the box, "as if to determine from which direction the sound came, and then marched straight toward the female." Will concluded from this that the ears of the beetle were located in its antennæ. Seeing that Will's experiment as described by him was incomplete, I took a pair of beetles belonging to the same family (genus *Prionus*), and determined the true location of their ears by a system of rigid and absolute exclusion. These beetles, when irritated, make a squeaking chirrup by rubbing together the prothorax and mesothorax. When I irritated the female she began to chirrup, and the male immediately turned toward the small paper box in which she was confined. I then removed the antennæ of the male, and again made the female stridulate: the male heard her and at once crawled toward her, although his antennæ were entirely removed. This showed conclusively that the organs of audition were not located in the antennæ, as Will supposed and as Lubbock advocates. I then removed the maxillary palpi of the male, after which the insect remained deaf to all sounds emanating from the female. Again, I took an unmutilated male, which at once turned and crawled toward the chirruping female. I then removed its labial palpi, leaving maxillary palpi and antennæ intact: it heard the female and made toward her. The maxillary palpi were then removed (the antennæ being left *in situ*), and at once the creature became deaf. If the maxillary palpi of long-horned beetles be examined, certain vesicular organs, each containing a microscopic hair, will be observed in the basal segments; these, I take it, are auditory vesicles. In some of the Coleoptera I have found auditory rods in the apical segments, though this is by no means a common occurrence. In Cicindelidæ and Carabidæ these auditory vesicles are exceedingly small, and require a very high-power objective in order to be clearly seen. In justice to other observers I must say, however, that I am inclined to believe that in all beetles the antennæ in some way aid or assist audition, but they are adjuncts, as it were, and not absolutely necessary. It is a matter of easy demonstration to show that some of these insects hear less acutely when they are deprived of their antennæ.

SOME PRACTICAL POINTS ON THE ADMINISTRATION OF CHLOROFORM.[1]

By LEO ETTINGER, M.D.,

NEW YORK.

A RECENT editorial on the subject of anæsthesia suggested to me the propriety of some remarks on the above subject. As may be observed, the suggestions are based upon personal experience largely, but it is to be hoped that they will meet with indulgent approval, though some may run counter to prejudices prevalent in this section.

I shall confine myself to chloroform anæsthesia, for which I possess a decided personal predilection. It may be conceded that a varied personal experience of some six years in its administration would justify the judgment that, properly administered, it is a practically safe and convenient anæsthetic. As a result of this experience, the writer is no party to the fear of the danger from chloroform so general among the practitioners of this city. I have also had some experience with ether, and such observations as I have made did not impress me favorably. Its administration is attended by such disagreeable features as the intense stage of preliminary excitement, the cyanosis and salivation, combined with the objectionable after-effects, the intense nausea and retching, lasting from twelve to forty-eight hours, seldom less than twenty-four, that *per se* it certainly cannot be deemed an eligible anæsthetic. All of these facts are more or less true of ether (and rather more than less), even in the most skilful methods of administration: and on the other hand chloroform is practically so free from them that, were the two of equal safety, chloroform would be decidedly preferable. It also seems rather difficult to judge the exact quantity of ether needed. In order to maintain the anæsthesia, its rather free use becomes absolutely necessary. In this respect, chloroform does, it seems, possess a striking advantage, as its administration can be gauged with the utmost nicety.

The only reason generally assigned for the preference for ether is its supposed superior safety as compared with chloroform. Other things being equal, this feeling, it must be said, is not shared by me. But so much has been said of the resultant pneumoniæ and nephritides, many fatal, that there arises the question of its actual safety. Some years ago, when the German hospital of this city substituted ether for chloroform, there was a rumor that more patients died within a week or so following operation than had ever died before from chloroform in a given period.

Now it is to be hoped that the charge of egotism may not arise against me, on asserting that, certain rules salted down with some judgment and intelligence

[1] Read before the Metropolitan Medical Society, May 25, 1897.

being followed, we have in chloroform an entirely eligible and practically safe anæsthetic for virtually all surgical cases. There are a few cases in which its use in the pure state would be inadmissible. It is to be questioned whether in these cases ether would prove any safer. When in such cases general anæsthesia is an absolute necessity, probably the alcohol, chloroform, and ether mixture (so called A.C.E. mixture), in the proportions of one, two, three, would be better. This is to be administered in the same way that chloroform is.

First, in the administration of chloroform the administrator must confine his attention to the narcosis, and to that and nothing else. This might seem a needless injunction, but as a matter of fact it is very rarely adhered to. Its importance cannot be overestimated. The respirations, facial appearance, and pulse should be continually observed. As to the face, stress is to be laid upon the appearance of the nose and lips. The jaw should be kept well forward to prevent swallowing the relaxed tongue. While cases may arise in which it will become necessary to pass a silk ligature through the tongue, personally I have never found it necessary to do so. In fact this should be a very last resort. When possible it is preferable to avoid even the tongue forceps, thrusting forward the angles of the jaw sufficing in nearly all cases. In determining the sensibility of the conjunctiva, the pulp of the ring finger placed over the outer part of the eyeball, and not over the cornea, should be employed. The cornea should not be touched at all, and the conjunctiva very lightly. In fact the relaxed state of the lids is usually a sufficient index to the depth of the anæsthesia. Conjunctivitis of a severe type, and even ulcer of the cornea, have been said to follow careless manipulations of the eye.

Here it may not be inappropriate to refer to certain of the relations between the *narcotiseur* and the operator. While the former, it must be conceded, should defer to the wishes and expressed desires of the latter, still in the actual conduct of the narcosis he should be free from any interference; for, if he is unfit to be trusted with his discretion, he is unfitted for the administration of the drug. On the other hand, he should not worry the operator with remarks about his patient unless it becomes necessary to discontinue the operation, either temporarily or absolutely.

The writer carries his armamentarium in a small box. The latter contains four small vials: one of alcoholic solution of nitroglycerin, 1 to 1,000; one of spirits of camphor; one of nitrate of strychnine of the strength of two grains to the ounce; and one of a solution as follows:

R Morph. sulph. ..... 1 c.c.
Atrop. sulph. ..... 0.02 "
Chloral. ..... 0.50 "
Aquæ dest. ..... ad 30 "
M. S. Magendie.

Besides this there is a tube of hypodermic tablets of digitalin, each one-one-hundredth of a grain. Then there is an Esmarch mask and a chloroform drop bottle. The mask frame is in two pieces, the one readily detachable from the other. The mask, which is thus easily removed, is made of Jaeger white stockinette. It is advisable to have a number of masks handy, so as to have a fresh one for each narcosis. The drop bottle should be only partly filled, and the larger tube should be always kept closed, the chloroform being poured drop by drop from the smaller one.

When expedient it is always well to be supplied with a jar of oxygen, or preferably of a twenty-five per-cent. mixture of nitrous-oxide gas and oxygen. This is a precautionary measure simply. Also it is well for the *narcotiseur* to have a nurse detailed for his special use. The latter is not absolutely necessary, but often proves a material aid. False teeth should be removed; also the condition of the heart should be ascertained. If the latter be not satisfactory, or the pulse be 120 or more to the minute in the absence of any acute inflammatory process, it would be better not to use a general anæsthetic. Or if the latter be inevitable, it will become necessary to modify the administration of the chloroform in such manner as shall be indicated farther on.

As a preliminary step to the administration of the anæsthetic, the hypodermic administration of from seven to ten minims of the morphine solution as above, preferably ten, is advised, except of course with children and when there is a distinct contraindication to its use. Of its great value the writer is convinced. It allows the anæsthesia to be maintained with much less chloroform, while at the same time obtaining the tonic effect of the morphine on the heart and the atropine on the respiration. This measure should precede all capital operations. For these the ten-minim dose should be employed. In fact, often as much as fifteen minims may be given with distinct advantage. Not only will it render the administration of the anæsthetic much easier and safer, but it will eliminate almost entirely all danger of surgical shock.

The chloroform should be administered drop by drop, and no more should be used than is absolutely necessary. It is surprising how far a little will go if carefully administered. It is my custom seldom to exceed a half-ounce for an operation lasting an hour and a half. Some time ago two ounces sufficed for nine different cases, including three laparotomies, all nine of not less than a half-hour duration, some an hour or more. A short time ago there came under my notice an account of a fatal case of acute hepatitis following the administration of two and a half ounces of chloroform during two and a half hours. Judging from experience, the writer has no hesitation in saying that about one-third should have sufficed. These results are attainable even without the use of morphine and atropine. When the latter are employed, even less will suffice. It is in this careful and guarded manner of administration that the safety of chloroform lies. Thus given, it is my impression that it is as safe as ether.

During the anæsthesia one should have at hand a twenty or twenty-five minim hypodermic syringe charged with the strychnine solution, in which two of the digitalin tablets have been dissolved, *i.e.*, provided in the individual case in question no contraindication to digitalin exists.

There are cases in which the administration of either chloroform or ether, as such, would be inadmissible. At the same time general anæsthesia may be an absolute necessity. In such cases, if no renal or pulmonary trouble exists, the A.C.E. mixture should be used. At the same time either oxygen or preferably the twenty-five-per-cent. nitrous-oxide mixture should be kept flowing constantly under the mask. If renal or pulmonary trouble coexists, chloroform itself must be used in conjunction with the gas as noted. The writer is contemplating the construction of a frame which will allow the administration of the oxygen at its lower part, while above is a detachable stockinette mask on which the chloroform is to be dropped for use in these cases. If otherwise permissible, the anæsthesia should be preceded by the hypodermic administration of from one-twenty-fourth to one-fifteenth of a grain of the strychnine nitrate, with or without the digitalin. During the operation, if no hemorrhage exist, the nitroglycerin solution should be used, the half or all of a syringeful at a time. Of course these measures are for this class of cases, and when otherwise the need might

arise. It is not intended that they should be routine practice.

Another ingenious modification of the chloroform narcosis is its alternate administration with pure nitrous-oxide gas, commencing with the chloroform and following with the gas, and from time to time repeating the chloroform.

The possible results attainable by one modification or other of the narcosis were recently demonstrated in a very satisfactory manner in two instances. The first was an extreme case. It occurred in the person of a short, very fat, parturient Bohemian. She at the time was suffering from the effects of a heart lesion of extreme gravity. That organ was enormously hypertrophied and dilated and presented loud aortic and mitral murmurs, both of insufficiency. The pulse was from 120 to 150 per minute, extremely small but rather tense. The patient was profoundly cyanotic and intensely dyspnœic. As above said, at this time she was in labor. Her physician, Dr. Chevcik, realized the gravity of the case, and called in Dr. S. Marx for council. The latter advised immediate delivery by *accouchement forcé*. Here the A.C.E. mixture was employed in conjunction with the oxygen gas, which was kept steadily flowing under the mask. The anæsthesia was preceded by the nitroglycerin solution injected hypodermically, repeated at intervals during the narcosis. After delivery the patient's condition was much better than before the operation. When the oxygen was exhausted, it was followed by the twenty-five-per-cent. nitrous-oxide mixture, kept up for some hours, while caffeine citrate and strychnine were injected hypodermically every two hours. That night, for the first time in months, she was able to lie upon her back. Two weeks later she died of an attack of acute œdema of the lungs, thus showing the extreme gravity of the heart lesion.

In the second case the patient, while exhibiting no urgent symptom, was much exsanguinated from repeated hemorrhages; her urine was loaded with sugar and albumin, and she weighed two hundred and ten pounds. Here the pure chloroform was used combined with the coincident inhalation of the nitrous-oxide mixture. The patient went through the narcosis without a single accident, and emerged from it in the best of spirits. Many similar cases could be cited.

The experiments of the Hyderabad commission indicate that chloroform primarily attacks the respiratory centres; further that it does not overwhelm the latter, but gives warning of approaching danger. This met with in time, in these experiments was always overcome. The writer's personal experience bears out the above in its entirety. As a measure of resuscitation, artificial respiration occupies the very front rank, especially when associated with pure oxygen or the twenty-five-per-cent. nitrous-oxide mixture, and it should always be employed. As adjuvants, the strychnine and nitroglycerin solutions, used as above, are of signal value. In the light of recent experience, Laborde's method of lingual traction is a measure of the greatest value, often attended by results when all else seems to fail, and its use should never be lost sight of. With children, suspension by the heels with artificial respiration is a very valuable expedient.

In conclusion, I have no hesitation in saying that chloroform, thus used with caution and judgment, is the anæsthetic *par excellence*. Its administration can be gauged with the utmost nicety; further, it is simple, and agreeable to both patient and *narcotiseur*. The rest is altogether a question of the intelligence, skill, and judgment of the latter. Were it a question of intrusting the anæsthesia to untried and inexperienced hands, ether would admittedly be much safer, but there is no valid reason for not exacting the above qualities in this field as we should in any other; and I am confident that when they are present chloroform is quite as safe as ether, and for other reasons far more eligible. Thus used it is practically free from danger, and never characterized by the disagreeable phenomena, both with and after, so common to the use of ether. In the vast majority of cases it should be used pure; in exceptional cases it may be modified as above indicated.

Progress of Medical Science.

Some Points of Preventive Treatment in the Diseases of Women.—Dr. A. E. Giles, writing in *The Hospital*, says that the first question here is of overstudy. Probably the average girl can acquire as much learning as the average boy; but to do so she requires bodily health and strength equal to his. Now the boy and girl work under different conditions, which if ignored lead to disaster. Let girls pursue their study, but more leisurely; they will arrive at the same goal, but a little later. Physically and emotionally a girl arrives at womanhood earlier than a boy arrives at manhood; this necessitates a corresponding saving of energy in some direction, and the direction in which this economy of energy is to be sought is in intellectual activity. Secondly, it should be impressed upon parents that premature emotional excitement is bad; sensational love novels should be avoided, and the "sex question" left dormant as long as possible. The idea that marriage is the only goal of a girl's existence should be discouraged, for, while it may be true that in the rôle of wife and mother the average woman is seen at her best, the preparation for this position is best attained, not by directly aiming at it, but by the development of physical health, by the training of the mind, by breadth of thought and widening of interests.

Methylene Blue in the Diagnosis of Renal Permeability.—Drs. Achard and Castaigne (*Le Bulletin Médical*, June 23, 1897) have applied the methylene-blue test to fifty new cases. In twenty-two cases in which the elimination of the blue was normal, five autopsies have shown the integrity of the kidney. Out of twenty-eight cases in which there was a tardy elimination, lesions of the kidney were found at thirteen autopsies. In this series three cases of urinary infection with suppurative pyelo-nephritis were found, one case of interstitial nephritis with considerable atrophy of the kidneys, cystic kidneys in a cardiac case without albuminuria, and a kidney presenting evidences of obstruction in a woman who died of uræmia. It was also noted in the case of circumscribed lesions of the kidney that the permeability remains normal if the remainder of the parenchyma is healthy. Variations of permeability and a return to the normal after recovery from acute disease, as in pneumonia, were noted; again, after finding a normal permeability in a tuberculous patient, there would be a sudden delay and albuminuria and anasarca would come on. This test is useful not only in medicine, but also in surgery, as it indicates whether the kidneys perform their functions in a normal manner. Dr. Schwartz reports a case of hydronephrosis in which catheterism permitted the urine from each kidney to be examined separately. The blue did not pass from the hydronephrosic side, and it flowed with some delay from the supposedly healthy side, from which side, too, the urine showed traces of albumin. Epithelial nephritis gives rise to an excessive permeability, according to Dr. Bard, who has not demonstrated this statement anatomically; however, the facts agree with the experiments of the authors.

Relative to the variations liable to occur from a defective absorption of the blue, it is found that even considerable œdema does not prevent the normal appearance of the blue in the urine and does not detract from the results of the test. To verify the state of absorption, injections of twenty grains of chlorate of sodium may be given, this substance being eliminated by the saliva and the urine at the same time, and possessing the advantage over iodide of potassium of producing no pain and no local irritation. The appearance of the chlorate in the urine is slower than in the saliva with subjects in whom defective permeability is also attested by methylene blue. As regards the technique of the procedure, it is advisable to make deep injections in order to avoid the formation of indurated nodules. It is also absolutely essential to employ methylene blue, since the other aniline blues do not give the same results. Methylene blue can be distinguished by examining a dilute solution with the spectroscope; it gives a dark line in the red portion, which the other blues of commerce do not give. Drs. Hauser and Voisin have inquired concerning the colorless derivative of methylene blue in the urine of patients submitted to the test. This colorless compound of methylene, when heated in urine with acetic acid, becomes green. This chromogene can be separated, as it is insoluble in chloroform. The colorless methylene above mentioned is not the same as methylene white. The chromogene can be transformed into the blue and administered in this state. In twenty-nine subjects a comparative study of blue and chromogene have been made. In nine instances the two substances appeared simultaneously after the normal delay of one hour. In nine patients there was an equal delay for both the blue and the chromogene. In cases having more or less profound lesions of the kidney as demonstrated by autopsy, the chromogene passed before the blue. The chromogene seems to be more diffusible and to traverse the diseased kidney sooner than the blue. In eleven cases there was a delay of the blue only, the chromogene appearing normally. Several clinical facts of this kind seem to show that in such cases there are functional disturbances of the kidney, two autopsies have shown degenerative lesions of the epithelium. To sum up: A delay of the same time in both blue and chromogene is a sign of defective permeability; a delay of the blue only is met with when the trouble with the permeability is less profound; functional trouble of the kidney may be the exclusive cause of a delay limited to the blue alone. A number of cases are cited, showing how useful this test may be in difficult diagnosis.

Hysteria in Early Life.—In *Pediatrics* of August 1st is a paper of much interest by Dr. Eshner on this important subject. Ideas concerning that form of neurosis known as hysteria have undergone a revolution, and the widespread belief that women alone were subject to this disease, though not quite extinct in the minds of some, has by the great majority been relegated to the limbo of the past. The French school, and especially Charcot, must be thanked for our improved knowledge of hysteria, and it may now be said to be a well-recognized fact that hysteria may attack men and even quite young children. When it occurs in infants the cause is, according to the English school, due to hereditary neurosis. Hysterical affections are often found at an early age in children of a neurotic predisposition. Clouston says in hysterical cases occurring in children there is no doubt "a pathologically premature development of the emotional brain centres due to bad heredity, and this is sometimes accompanied by a premature sexual development." Dr. Eshner says that the disorder has a pathology of its own, as he believes the results of future investigations will demonstrate; but as yet we need more knowledge, especially in the domain of physiological and pathological chemistry, before we may hope for a solution of this aspect of the problem. Dr. Eshner reports eight cases in his paper, which, although not all quite typical, possess instructive features.

Radiant Heat in Ulcers of the Leg.—Dr. Colleville describes in the London *Lancet*, May 29, 1897, a simple way of treating ulcers of the leg by heat without any very elaborate apparatus. A square plate of metal that will stand heating and a Bunsen burner are all that is required. The metal is brought to a dull red heat by the burner and the ulcer is exposed to this heat at a distance of about ten inches, the remainder of the limb being protected by a bandage. The temperature is about 45° C., which is easily borne and the burner is regulated to maintain the heat at just this point during the whole of the sitting, which lasts from twenty minutes to an hour. This glazes the surface, and large granulations are visible through the thin semitransparent coating. It is best to leave the ulcer exposed to the air for some time and to be careful in dressing the wound not to touch the surface with aseptic gauze or other materials used. Some improvement is generally noticeable after the first sitting and the wound is cicatrized after from five to twenty-five sittings. In the later sittings, when the ulcer is almost healed, a more moderate degree of heat may be used. When gas is not available, the sun or the heat of a fire may be utilized. The beneficial effects of the treatment are attributable to the combined action of heat, light, and ventilation.

Two Hundred Cases of Serum Diagnosis.—Dr Gasser reports in *La Presse Médicale*, June 26, 1897, that he has had occasion to use the serum diagnosis of Widal in two hundred cases. In each of these the diagnosis of typhoid fever was questionable on the first day of clinical observation. He has constantly used Widal's extemporaneous process with a mixture of one to ten. In one hundred and twelve of the doubtful cases the reaction was positive. This reaction took place in one case on the third day, once on the fourth day, twelve times on the fifth day, and on the eighth to tenth day in the others; that is, from the time that the patient entered the hospital. In one case the reaction did not take place until the twentieth day. Dr. Gasser was able to test on himself the disappearance of the agglutinative power. He entered upon his convalescence May 29, 1897, and October 1st his serum was still agglutinative, but it was no longer so on November 1st. He has tried the reaction in a large number of cases suspected of being typhoid fever, complicated in fifty-two cases with gastric fever, in thirty with continued marsh fever, in five cases with phthisis, in one with generalized subacute tuberculosis, and in two with true pneumonia. In all these cases the reaction was negative save in the two pneumonias. In these two instances the measure of the agglutinative power was not known. For one of the cases the reaction was sought by the slow process; the clarification of the tube was observed after boiling a mixture of one part of serum to twenty parts of bouillon. Perhaps these two patients had been under the influence of a frustrated typhoid infection. One of them lived in a locality that had furnished a certain number of typhoid cases, the other had suffered from diarrhœa for a short time before entering the hospital. In a large number of cases examined the diagnosis was difficult and doubtful, and the reaction of Widal has proven a very useful guide.

Intestinal Antisepsis.—Dr. Heinrich Stein (*Centralblatt für die gesammte Therapie*, 1897, vii., 321) enumerates the various agents by means of which in-

testinal antisepsis can be obtained. In abnormal acidity he recommends calcium carbonate (two and one-half drachms per day in one-grain doses) or magnesia (ninety grains per day). Creosote, guaiacol, and resorcin are useful; their action is shorter but they may act after absorption on distant areas. Menthol (one and one-half grains twice or thrice daily), naphthalin (one and one-half to seven grains at a dose or seventy-five grains per day), thymol (one and one-half grains several times daily in alcoholic solution); this latter is an excellent parasiticide. Since absorption limits the action of the drug in the intestine various antiseptics have been prescribed with insoluble substances. salol, parachlorsalol, kresosalol, beta-naphtholsalol, or betol, the latter being slightly poisonous. These are broken up in the intestine by the action of the pancreatic juice and by unformed intestinal ferments into salicylic acid and kresol, etc. Other substances proper for this purpose are benzonaphthol, ammonium sulpho-ichthyolate, salophen, etc. The absolutely insoluble antimicrobic remedies can be given in much larger doses; such are phenolbismuth (fifteen to forty-five grains per day), the same dose for kresol-bismuth, chlorophenol-bismuth, bismuth salicylate, zinc salicylate, trioxymethylen. For irrigation solutions of salicylic acid in sterilized water (one to two parts per thousand), silver nitrate (two-tenths to five-tenths per thousand), boric acid (five-tenths per hundred), creolin (one one-hundredth to two one-hundredths per hundred), tannin (two to five per hundred). Applications of an insoluble antiseptic powder, as afforded by the bismuth preparations, may be used during irrigation.

Treatment of Erysipelas.—Dr. H. Koster (*Therapeutische Monatshefte*, 1896, vi., 299) states that painting the affected parts twice daily with vaseline and covering the application with linen and fastening with a gauze bandage has given good results. In addition to this the treatment is purely symptomatic: for headache, acetanilid or antipyrin; if the temperature is above 104° F., quinine in seven-grain doses; if cerebral symptoms are present, ice bag to the head, and a cathartic such as calomel or senna; for delirium, chloral; for heart weakness, digitalis and alcohol. One hundred and thirty patients treated in this way show results equally as good as those obtained by other methods. The duration of the fever is the same as when lead lotion, painting with iodine, ichthyol-vaseline, or sublimate-lanolin are resorted to. By this method extension of the process takes place about as frequently as when other methods are used. Complications by phlegmonous processes are no more frequent in this method, which presents no danger of exciting untoward symptoms, such as burning or poisoning, and it possesses the additional advantage of being inexpensive.

Abscess of the Liver Six Years after Tropical Dysentery.—At a recent meeting of the Académie de Médecine, Berger (*Gazette hebdomadaire de Médecine et de Chirurgie*, July 18, 1897) related the history of a man who had suffered from dysentery in Tonquin six years previously, in association with congestion of the liver. The latter yielded to the application of a blister. On returning to France at the end of six months he was again seized with dysentery, which lasted for three years. In the sequence of an attack of influenza six months before he came under observation, acute pain appeared in the hepatic region followed by tumefaction in the right hypochondrium. At the same time there were loss of appetite and emaciation, though but little fever. The upper limit of hepatic percussion dulness reached to the level of the third rib. A diagnosis of abscess of the liver was made and evacuation proposed, but the accumulation ruptured into the lung and was being gradually expectorated. The patient, however, continued to fail and it was decided to attack the abscess directly. In accordance with the evidence yielded by physical exploration, ten centimetres of the seventh and eighth ribs was resected, the seventh intercostal space and the diaphragm were incised, and a large abscess in the liver was disclosed. This was drained and tamponed. The expectoration at once subsided, the cavity gradually diminished in size, and in the course of a month and a half the patient was restored to health.

Percussion of the Spleen.—Dr. Bäumler (*Wiener klin. Wochenschrift*, 1896, No. 40, p. 909) thinks that we can ascertain the size of the spleen by percussion better than by palpation, as is usually done. He holds that a large spleen can rarely be detected by palpation even when there is no tympanites, while even moderate enlargement can be made out by percussion. He says that dulness in an oval area seven to eight by ten centimetres indicates enlargement. It is important to percuss with different degrees of force in different parts in order to avoid the difficulty caused by the position of the thin spleen between organs of different degrees of resonance. Dr. Bäumler holds that even the posterior and upper parts of the spleen can be made out. Usually the diagonal position of the patient is best, but sometimes it is well to try various positions. Dr. von Ziemssen agrees in general with Dr. Bäumler, and urges the desirability of marking out and measuring the area of dulness.

Wine and Cirrhosis.—M. Lancereaux, who is one of the greatest living authorities on the action of alcohol, has lately given his opinion with regard to the true cause of drinkers' cirrhosis. His conclusions are deduced from personal observations of two hundred and ten persons addicted to drink in Paris. M. Lancereaux disputes the statement that the usual cause of cirrhosis is the consumption of an excess of alcohol, but says that it is due to drinking large quantities of wine, and especially of red wine. He lays the blame upon the potassium salts, and gives the result of certain experiments made upon animals. By means of these experiments it was proved that potassium salts when administered to animals usually killed in from fifteen to eighteen months, and cirrhosis was discovered in the majority of them. M. Lancereaux demonstrated by other experiments the fact that alcohol taken in excess produced fatty degeneration of the hepatic cells and subsequently fatty cirrhosis. The final conclusions arrived at from this series of experiments were that wine, and plastered wine in particular, is the cause of atrophic cirrhosis.

The Treatment of Chronic Articular Rheumatism.—Dr. Ott, in his address before the German Congress of Internal Medicine, June 9–12, 1897, recommended woollen clothing and especial attention to the diet, with meat as a foundation, together with eggs, fish, vegetables, butter, and cheese; especially milk. Water is the best beverage; alcohol and the carbohydrates should be much restricted, moral depression avoided; a journey may be found beneficial in some cases. Treatment should be prompt and meet every stage of the disease, which should be carefully watched even long after convalescence. Acute symptoms must be surmounted by every possible means—fever, by repose in bed and restricted diet; local pains and swellings, by Priesnitz compresses, liniments, or salves containing opiates, or by injections of morphine. Absorption is hastened by painting with iodine. Puncture is useful in severe swellings; so, too, the elastic bandage. Some observers find salol beneficial; others prefer antipyrin, acetanilid, phenacetin, etc. When

there is swelling of the joints without much loss of mobility or dislocation of the ends of the bones, external treatment is indicated, such as will favor absorption. Tincture of iodine and ichthyol are sometimes successfully employed. Baths should be recommended when there is no acute or subacute inflammation, but should be suspended as soon as inflammatory symptoms reappear. In all baths the main point is heat. This can be attained by the new partial steam and hot-air baths; mud baths produce a mechanical stimulation of the surface beside the effect of heat, and hot mud compresses have been found useful in weak patients. The simple hot springs have been found useful for persons of great nervous excitability. The success of sulphur baths is probably due to the heat. The speaker also recommended hydriatic processes which combine hot and cold baths, to tone up a system debilitated by the effects of heat. In the raw seasons it is better to resort at once to the hydriatic process. He also recommends active and passive movements. The most favorable climate for persons affected with polyarthritis deformans should be warm, dry, and sheltered from winds, with hot springs convenient. Battaglia and Ischia in Italy, and Algiers, fulfil these conditions. Medication should aim to strengthen and tone up the system. Iron, quinine, and cod-liver oil are indicated. Singer has cured one case of typical acute rheumatism with intravenous injections of sub limate.

Goat's Milk as a Food for Children.—Since the observations of Schwatz have been published, considerable interest has been taken in the spread of tuberculosis by the use of cow's milk, and as a remedy it was proposed that all such foods should be boiled before being used by the infant. Since that dictum was promulgated, further chemical analysis of boiled milk has shown that the nutrition of the fluid is greatly reduced. Keer has demonstrated that fresh unboiled cow's milk contains fat globules with granular contents, which are immediately taken into the blood to build up the cellular structure, while cooking totally destroys this constituent; the fluid albuminoid constituent is also so much transformed that it is difficult to dissolve and assimilate in the alimentary canal. He is persuaded that milk should not be boiled when its nutritious value is required, and he therefore proposes the milk of goats for the feeding of children, as this animal is immune from tuberculosis. He further proposes the precaution of having the vessels containing the milk sterilized and covered to prevent aerial germs from infecting the food. Another advantage in the goat's milk is the constancy of its constituents, owing to the animal carefully selecting its own food and avoiding a great quantity of fluid matter. It can be fed in the stall with the same ease and satisfaction as the cow.—*Vienna Cor. Med. Press and Circular.*

To Combat Syphilis.—Dr. Chistiakov, of St. Petersburg, in a paper on the prophylaxis and therapy of syphilis, says that treatment should be both specific and general. Results are the best when the case comes under observation early. Treatment should be persisted in after the symptoms have disappeared in order to prevent their return. During a relapse we must return to specific treatment. In regard to the different processes of administering mercury, and their relative value, he says that when mercury is given by the mouth its absorption is very slow and the result mediocre. When friction is resorted to, the mercury is sometimes absorbed in too small a quantity and sometimes in too large an amount, consequently the results are uncertain. When injections are used, absorption takes place with more regularity, and the results are more definite. Experiments have convinced the author that the best method of administering mercury is that which can be varied according to the period of the disease and the condition of the patient. All methods have their inconveniences. The introduction of mercury by the digestive tract may cause gastro-intestinal trouble, friction may poison those about the patient, and injections may produce serious local affections. Hence, we should avoid giving mercury by the mouth when there is gastro-intestinal trouble, and avoid friction when the skin is disposed to erythematous eruptions, and avoid subcutaneous injections in nervous individuals and in children. Frictions to succeed must be carefully carried out and injections must be frequently repeated. Intramuscular injections of salicylate of mercury in suspension in oil or sterilized vaseline are one of the best means of administering mercury, the dose used being one to one and one-third grain every third, fifth, and seventh day for the first injections. We must not forget that specific treatment predisposes to certain affections, such as stomatitis, gastro-enteritis, anæmia, etc. Often these depend on causes outside the treatment and produce a temporary intolerance for specific treatment. It is necessary to eliminate the cause and accustom the system to specific medicines. Iodide of potassium is an excellent therapeutical agent in the secondary and tertiary stages, but to prevent relapses it is necessary to combine it with mercury. All means that tend to strengthen the organism should be employed concurrently with the specific treatment. Transform the pathological condition of the patient, give him strength enough to withstand new manifestations of syphilis in the intervals of treatment and care for him as a convalescent. A syphilitic may marry after five years without infecting his wife and producing syphilitic children. This term may sometimes be shortened to three years if the patient has been well cared for and during the second and third years has had no secondary or tertiary manifestations, and if he adopts preventive treatment before as well as after marriage. To diminish the influence of syphilis on posterity, specific treatment is recommended during pregnancy when there are any symptoms of the disease in the pregnant woman; when the woman becomes pregnant during the first five years of her disease; and when signs of syphilis were observed in her last pregnancy; when there existed secondary manifestations in her husband at the time of conception.

A Contribution to the Knowledge of the Anatomy of the Levator Ani Muscle.—Dr. William W. Browning, of Brooklyn, concludes a paper (*Medical News*, June 12th) with the following propositions: 1. That in the human subject it belongs to the class of rudimentary muscles. 2. That the weakness of its origin as well as the direction and the insertion of its fibres is consistent with such design. 3. That it is unphysiologic for a muscle to furnish a continuous support. 4. That the recto-vesical fascia is in itself sufficient, when intact, to afford the required support. 5. That the muscle is no better developed in the female (in whom support is most required) than in the male.

Abductor Paralysis in Stricture of Œsophagus.—In a recent issue of *The Hospital* some practical observations are made by Drs. Felix Semon and Savery in commenting on a case of bilateral paralysis of the abductors, due to malignant stricture of the œsophagus. While more or less incomplete paralysis of both these nerves is of not infrequent occurrence, complete bilateral paralysis is rarely met with, owing to the fact that death almost always occurs before the lesion has caused the paralysis to be complete. The case observed teaches that, in addition to complete aphonia and dyspnœa,

the latter on exertion only, another important symptom may result from the complete paralysis, viz., the impossibility of taking nourishment in the ordinary erect position. The explanation is that when both recurrents are paralyzed the closure of the glottis is impossible, and food and drink are therefore apt to pass into the larynx. But the mucous membrane of the larynx is supplied by the internal branch of the superior laryngeal nerve; hence sensation is not affected, and cough ensues when the food particles enter the larynx. The position recommended by Wolfenden for cases of painful dysphagia was found to be successful, viz., horizontal position on the side, with the head well over the edge of the bed; fluid nourishment is to be taken through a feeding-cup inserted into the lower angle of the mouth. When taken in this position the fluid passes, not over, but by the side of the larynx through the hyoid fossa, and penetrates into the œsophagus without coming in contact with the posterior surface of the larynx.

The Indigestion of Breast-Fed Babies.—It is stated in the *Archives of Pediatrics* that for many reasons less attention has been paid to the gastro-intestinal affections met with in breast babies than in those nursed artificially. Breast milk is the natural and ought to be the sole food of the infant, under physiological conditions, during the first year of life. Unfortunately there is too often a departure from the normal state, and the child, perhaps also the mother, may suffer during the lactating period. The natural pride and instinct of the mother are apt to lead to the presumption that all is going well with her and the infant, when in reality she is not a good nurse, and the child is suffering more or less. In America the question of infant-feeding in all its aspects has received the attention which it deserves, and which it has not met with in England. The greater prevalence of diarrhœal disease during the tropical summer of the American continent has stimulated study and research on this important subject. Milk laboratories have been established in the larger cities, and the feeding of infants has been placed on a comparatively sure and scientific footing. Owing to the researches of such men as Jacobi, Rotch, Holt, Lewis Smith, Meigs, and others, we are now furnished with scientific data to guide us in the study of the subject. In the writer's own country the question of milk supply is now receiving some attention from sanitarians, but there is as yet no ready means available to the general public of obtaining pure or properly sterilized milk in quantity, nor of having milk analyzed or tested in laboratories established for the purpose. Whenever the milk of the mother is defective in quantity or quality, the child is apt to suffer. It does not thrive or grow at the normal rate. Instead of being plump and firm and happy, it is soft and flabby, and is always crying, and never appears to be satisfied. Its skin is harsh and dry. The tongue is somewhat red, often slightly furred. Vomiting from gastric catarrh is not infrequent. The stools are unnatural, and present various appearances depending on the quality of the milk. They are generally loose, and seldom have the natural mustard color or consistence; but are usually pale, and often of an ashy gray color, sometimes greenish, or mixed gray and green. The soft curd of the mother's milk is present undigested in little granular-looking masses. There is an excess of mucous secretion, sometimes there are little streaks of blood. As a rule, indigestion of mother's milk is more frequently intestinal than gastric, diarrhœa being more common than vomiting. This appears to be largely due to indigestion of the fatty and proteid elements of the milk. Infants, in regard to their digestive capabilities, are but little men and women, and it is certain they have their idiosyncrasies likewise. The milk of a mother seems to be suited to her own child under physiological conditions. Irregular suckling is one of the commonest causes of indigestion in babies. It produces a milk too concentrated, which inevitably causes indigestion in the child. Regulation of the suckling is generally sufficient to give relief. Irregular suckling may be due to two principal causes. It may occur in cases in which the milk is normal in quantity and quality, from bad habit on the part of the mother in being over anxious about her child, and carelessly giving it the breast at irregular times or whenever it cries. The more frequent cause, however, is deficient quantity of milk. In this case the child is unsatisfied and gets the breast too frequently in consequence, with the result that the milk becomes too concentrated and causes indigestion. The remedy is the addition of some substitute feeding. Inseparably connected with the question of maternal feeding is the no less important one of the artificial rearing of infants who are unable to obtain breast milk. The huge mortality of infants under one year is hardly reduced to a lower level than it was half a century ago, when in England and Wales no less than 76,328 children under twelve months died, out of a total of 350,101 deaths in one year. Want of breast milk and bad artificial feeding are largely responsible for this. Surely it is our duty, as a profession, to try and stem this tide of mortality. There is no way to attain this end but by education: and let us hope in the near future that we will be in a better position in this respect, and have greater facilities for showing good results in what, it must be admitted, is an important branch of preventive medicine, too much neglected.

Postpuerperal Endocarditis of the Left Heart Propagated to the Right Heart by Perforation of the Septum.—An interesting observation by Dr. Charrin is found in the columns of the *Milwaukee Medical Journal*, as follows: The patient, a woman of twenty-three years, was taken three weeks after confinement with intense headache, anorexia, severe lumbar and epigastric pains, palpitation, swelling of the face and eyelids, and œdema of the extremities. When she entered the hospital, the face was pale, there was considerable weakness, and she had some metrorrhagia. The respiratory apparatus presented a few râles of congestion at the bases. The intense dyspnœa was evidently caused by a cardiac lesion. At the apex was heard an intense souffle and from time to time a systolic *piaulement*. On the following days appeared a go-and-come bruit at the middle part of the heart: at the apex there was an almost metallic resonance: there was no *frémissement*. The dyspnœa increased, and during the evening the patient expectorated hæmoptoic sputa. Delirium supervened and the patient died during the night. Autopsy: Blood from the heart sown on different media remained sterile. The endocardiac vegetations alone gave cultures of staphylococcus aureus. The right ventricle contained a fibrinous clot. The aortic sigmoid valves presented vegetations which completely deformed them: these vegetations were ulcerated, the valves perforated. There was no valvular aneurism. At the site of one of the valves existed a perforation of the interventricular septum, establishing a communication between the two ventricles. On the upper surface of the left leaflet of the tricuspid valves existed a pediculated polypoid vegetation at whose base opened the interventricular fistulous tract. There was nothing on the mitral valve. At the apex of the left lung was an infarct, black in color and of the size of a small apple. The right lung was œdematous but still crepitating; at the base of the lower lobe existed a large infarct. In a pulmonary vein, at this

level, the clots were almost puriform. The uterine mucosa was red, the cavity dilated; and there was thrombosis of the uterine veins without true suppuration. The most interesting revelation was the communication of the two ventricles by ulceration of the septum and the probable propagation by that way to the tricuspid. The lesions, already remote at the time of autopsy, were probably produced shortly after labor, remaining latent for some time. This communication, produced at the site of congenital lesions, permits us to suppose that in the latter the mechanism may have been also an endocarditis.

Latent Ulcer of the Stomach.—In a late number of *Health* an account is given of a remarkable case of latent ulcer of the stomach, which came under M. Dieulafoy's observation. The first symptom which manifested itself was perforation, there had been no previous gastric symptoms, no dyspeptic troubles, and no vomiting of blood. The patient was a young woman who was apparently in good health, although about two months before she had complained of pain in the stomach, to which, however, she did not attach much importance. Her appetite was good and she never complained of indigestion, and on the day that perforation took place she performed her usual work and appeared to be perfectly well. Shortly after dinner she was suddenly seized with a horrible pain in the epigastric region, and a physician was called. But he could not make an exact diagnosis, and, thinking that it might be a case of hysteria, prescribed an enema containing laudanum. On the following day M. Dieulafoy saw the patient. The pain was then somewhat mitigated, but it extended over the entire abdomen; the abdominal wall was tense rather than swollen, and the slightest touch or pressure over the abdomen was intolerable. The pulse was frequent, but the general condition was rather good; the expression of the face was not anxious; there were no peritoneal facies, no hiccough, and no vomiting. However, M. Dieulafoy gave a diagnosis of generalized peritonitis, and the patient was immediately taken to the hospital, where an operation was performed. At the time of her admission the temperature was 101.6° F., and the pulse 120. The abdomen was swollen and tense. Median subumbilical laparotomy was practised, and when the abdomen was opened a stream of yellowish liquid escaped. The intestines appeared to be congested, and their surface presented creamy-like false membranes of recent formation. The appendix was found to be in a healthy condition, and the genital organs were not involved: the seat of the peritoneal lesion was evidently the upper part of the abdomen. During the exploration the patient's general condition became so aggravated that it was not thought prudent to lengthen the incision and prolong the operation; so the abdomen was closed after the peritoneum had been subjected to lavage with boiled water. The patient died on the following morning. At the autopsy the integrity of the appendix and the genital organs was verified, but on the anterior surface of the stomach, at a distance of about a centimetre from the small curvature, and at an equal distance from the cardia and the pylorus, a large perforation was found; it was of about the size of a florin, and its borders were not thick; there were no surrounding peritoneal changes. On the posterior surface of the stomach there were some adhesions which united it with the pancreas; these adhesions were very loose, and were easily torn away with the finger. They surrounded a second perforation, which corresponded exactly in size, shape, and situation with the first one. The appearance of these ulcers resembled the classic type of simple ulcer of the stomach, and they had certainly existed a long time before perforation occurred. It is incomprehensible, says M. Dieulafoy, how an ulcer which was serious enough to cause perforation could have remained completely indolent; it is possible, he thinks, that symptoms had manifested themselves at some time, and that they had been forgotten by the patient or neglected by those who observed them. M. Dieulafoy thinks that this case demonstrates that, in the presence of a sudden attack of peritonitis, the physician should not attribute it only to appendicitis, salpingitis, intestinal perforation, or perforations of the biliary tracts, but to perforations of the stomach as well, although there may be no history of previous gastric troubles. At the present time, he says, when surgical intervention in peritonitis is of daily occurrence, an early and correct diagnosis may, in favorable cases, assure the recovery of the patient.

The Removal of Cancerous Gall-Bladder.—Heidenhain has recorded the case of a woman, aged sixty-one, who during nine months previous to admission to hospital had suffered from pain in the upper part of the abdomen, with occasional severe exacerbations. At this time the liver dulness began at the fifth rib, and did not extend below the costal margin in the mammary line. The enlarged gall bladder was very distinctly felt, and presented an uneven surface, attributed to omental adhesions. The abdomen was opened by an incision along the outer edge of the right rectus muscle. Extensive adhesions had to be separated. The enlarged gall bladder and adjacent part of the liver were drawn out of the wound. The liver in the neighborhood of the gall bladder was grayish-white in color, which was attributed to interstitial changes. The walls of the gall bladder were much thickened, and gall stones were easily felt inside it. An incision into the wall of the gall bladder showed that it was the seat of malignant disease. The cavity of the gall bladder was accordingly not laid open, but a portion of the liver, with the gall bladder, was resected by means of Paquelin's cautery. The cut edges of the liver, as well as its general surface so far as it was open to examination, showed no evidence of malignant disease. The cystic duct was ligatured and divided and the whole removed. The patient made a good recovery from the operation, and was discharged six weeks later. There was a stone as big as a walnut in the gall bladder, and eighty-four smaller stones of the size of a pea were also found. The mucous membrane of the gall bladder showed papillary excrescences. Microscopic examination of the liver substance also revealed malignant disease. The prognosis appeared here to be fairly good, as the growth seemed to be limited to the parts removed. Early diagnosis of carcinoma of the gall bladder is hardly possible, and the case is usually too far advanced for operation when it is discovered. Courvoisier, in one hundred and three collected cases of carcinoma of the gall bladder, found gall stones in seven-eighths of the cases. The more it is recognized that long-continued gall-stone disease is best treated by operation, the more often will it happen that carcinoma of the gall bladder will be capable of being dealt with.—*Deutsche medicinische Wochenschrift.*

The Requisites of a Pure Water Supply.—Krauss (*Cleveland Journal of Medicine*, March, 1897) says 1. That the water supply of any city or village should not in any possible way be liable to pollution or contamination from the sewage of any other community. 2. That the sewage of a city should not be emptied into any watercourse not having a current of three to five miles per hour, and then the sewage entrance should be at a distance of one mile or more from the intake. 3. That when the water supply of any

city or village is a navigable stream, the water should be sand filtered before being pumped into the reservoirs or water mains. 4. That for ordinary drinking-purposes the water should not be taken in its primitive or raw state, but be either filtered, boiled, or distilled and aerated. 5. That not only chemic but bacteriologic examinations of the water should be made, at least once weekly, to determine its character as a safe or dangerous water for domestic use, and if contamination is shown to exist the services of an engineer should be enlisted to detect if possible the cause and origin of such contamination.

Chloroform versus Ether.—Gay says that the accumulated testimony of the past fifty years tends to prove conclusively that ether kills slowly, chloroform quickly; that ether kills by asphyxia, chloroform by cardiac paralysis; that ether gives plenty of warning, chloroform often none whatever; that ether is safer in healthy and strong people than in the weak and prostrated, but that chloroform is nearly as fatal in the vigorous as in the debilitated. Ether does not demand any especial skill in its administration; chloroform does. Proper treatment easily and effectually overcomes the unfavorable symptoms from ether; treatment often does no good whatever in accidents from chloroform. In short, ether is the safest general anæsthetic known; chloroform is not.—*Boston Medical and Surgical Journal.*

Chemical Examination of Human Breast Milk.—Adriance (*Pediatrics*, vol. xiv., No. 2) sums up a report upon the chemical examination of two hundred specimens of human breast milk, as follows: 1. Excessive fats or proteids may cause gastro-intestinal symptoms in the nursing infant. 2. Excessive fats may be reduced by diminishing the nitrogenous elements in the mother's diet. 3. Excessive proteids may be reduced by a proper amount of exercise. 4. Excessive proteids are especially apt to cause gastro-intestinal symptoms during the colostrum period. 5. The proteids, being higher during the colostrum period of premature confinement, present dangers to the untimely born infant. 6. Deterioration in human milk is marked by a reduction in the proteids and total solids, or in the proteids alone. 7. This deterioration takes place normally during the later months of lactation, and, unless proper additions are made to the infant's diet, is accompanied by a loss of weight or, again, is below the normal standard. 8. When this deterioration occurs earlier, it may be the forerunner of the cessation of lactation, or well-directed treatment may improve the condition of the milk.

A Study of Chlorosis.—Dr. Simon (*American Journal of the Medical Sciences*, April) concludes: 1. An anatomical basis of chlorosis has not been satisfactorily determined. 2. A perversion of the appetite—excessive consumption of starches and sugars—is a common symptom of chlorosis. 3. The development of chlorosis is due to an insufficient consumption of animal proteids. 4. Chlorosis is far more common than is generally supposed, and occurs in both sexes and at almost all ages. 5. The diagnosis of chlorosis should be based altogether upon an examination of the blood. 6. The term chlorosis should be discarded, and "simple anæmia" substituted. 7. Iron is not a specific in the treatment of chlorosis. 8. In the treatment of the disease attention should primarily be directed to the diet. 9. In cases in which iron fails satisfactory results may be obtained, without medication, from a suitable diet, in which animal proteids, bone marrow, and dark beer are the principal factors. 10. The beneficial effects of bone marrow are not due to the amount of iron which it contains.

Epidemic Mastitis.—The Budapest correspondent of *The Lancet* cites an epidemic of mastitis, occurring in twelve women, in all of whom the disease developed during the first week following childbirth. In none could the disease be traced to lesions of the skin covering the nipples or to sores in the mouths of the suckling infants. All of the patients had, however, been attended by the same midwife, who it was learned had charge of an infant suffering from stomatitis, and who was assumed to be the channel of infection. The mastitis ran a course different from that usually observed. The onset was marked by a severe rigor, which was soon followed by hyperpyrexia, swelling of both breasts, and rapid formation of deep abscesses. Incisions liberated a quantity of thick pus, which was found to contain large numbers of streptococci and staphylococci. The healing of the abscesses, though appropriately treated, was somewhat protracted.

Pregnancy in a Rudimentary Uterine Horn, with Rupture and Death, Probable Migration of Ovum and Spermatozoid.—Cullen and Wilkins (*Johns Hopkins Hospital Reports*, vol. vi., 1897) have reported the case of a married woman, twenty-nine years old, who had previously borne a child and died in the fourth month of pregnancy with signs of hemorrhage. Death occurred six hours after rupture of the fœtal sac. Upon post-mortem examination the abdominal cavity was found to contain four thousand cubic centimetres of blood and a fœtus of three or four months' development. The uterus consisted of a well-developed right horn, to which was attached by a muscular band an impregnated left rudimentary horn. The latter had ruptured, and the corpus luteum was found on the side opposite to that of the pregnancy. Microscopically the right, well-developed uterus was shown to possess a typical decidua, and the right tube contained the remains of the placenta lying free in its cavity. The cells of the corpus luteum resembled closely normal decidual cells. The pedicle joining the two horns contained a canal five millimetres in diameter, lined by a single layer of cylindric epithelial cells resting on a delicate stroma, external to which was a longitudinal muscular coat, and covering this in turn a coat of circular muscular fibres. The canal was closed at both ends, and there was no communication between the two horns. Migration of the ovum and spermatozoid occurred probably by way of the abdominal cavity. It is pointed out that cases of this kind are rare, rupture usually taking place between the fourth and fifth months and the patient dying with signs of internal hemorrhage. Some, however, advance to term, and two classes can be established: (1) those attended with rupture; (2) those in which rupture does not take place. Anatomically these cases differ from those of tubal pregnancy, in that the uterus is flexed toward the side opposite to the pregnancy, in that the pedicle of the fœtal sac springs from the uterus at the internal os instead of where the tube comes off, and in that the round ligament springs from the outer side of the sac instead of from the uterus. Clinically the symptoms of tubal pregnancy and of pregnancy in a rudimentary uterine horn when rupture has taken place are virtually the same. On examination of the uterus, however, the sound reveals that in the latter case the canal is flexed at the internal os and the uterus deviates to the side away from the tumor. The pedicle of the sac commences at the internal os instead of at the uterine cornu, and is usually of sufficient length to allow free mobility of the impregnated rudimentary horn. The treatment consists in amputation of the impregnated rudimentary horn. Migration of the ovum and spermatozoid occurs frequently when the impregnation of a rudimentary uterine horn takes place.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 43, 45, & 47 East Tenth Street.

New York, October 16, 1897.

THE CHARITY ABUSE.

WITH the commencement of the college terms and with the necessarily more active clinical work in the metropolitan hospitals the struggle for clinical material will be proportionately manifest. Thus it is to be reasonably expected that the old abuse of medical charity will boom along as destructively to the higher interests of the profession as ever, and will revive the old complaints against the atrocious unfairness of the entire system. It is some comfort to know, however, that the large majority of a suffering profession is still on the side of radical reform, and has not yet lost heart in its efforts to right a most grievous and far-reaching wrong.

In witness of this indication we note that one of the papers which called forth a very extended discussion at the meeting of the State Medical Association was upon the subject named. Dr. Wiggin certainly handled the abuse of charity in a straightforward, sensible, and practical way. It was the old story retold, but it always bears rehearsal at a time when the young practitioner is wearily waiting for business and weighing his chances for ordinary success against very heavy odds. The fight against the abominable evil of indiscriminate medical charity is now one for actual existence as a profession. Think of the statistics quoted by Dr. Wiggin from Dr. Stephen Smith's report! Either we are living in an age of pauperism or else charity, pure and simple, is an outrageous lie! What answer is there to the statement, founded on the study of the present dispensary and hospital systems, that fully forty-nine per cent. of the entire population of New York are virtually unwilling to pay for private medical attendance? It is not difficult to explain the reason for this when we look into the outrageous methods of free treatment as carried on at the Vanderbilt Clinic for all classes of pretended paupers, and when we note the gross wrongs connected with the well-advertised bids for pay patients at the Roosevelt and other ostensibly charitable institutions. Even the Sloane Maternity levies a mortgage on the good intentions of the coming mother by offering to care for her during her confinement, for sums varying from fifteen to twenty-five dollars for her entire term. How about the new lying-in hospital founded by a multi-millionaire for so-called charity, which institution, to prove its reason for being, must have its beds filled at any cost to the self-respect of the patient or the ultimate impoverishment of the doctor? The boards of managers draw the line between the propriety and impropriety of the thing, and the profession is expected gracefully and resignedly to toe the mark. But we still maintain that there may be hope for us yet.

The best of all indications is that the public in general is beginning to understand the true situation of affairs. The daily press and the pulpit are inclining to attack the questionable motives of the so-called Christian philanthropists. The more the subject is ventilated the better will it be for the real truth. It is quite true, as claimed by one of the speakers at the meeting in question, that the profession is very much to blame for tacitly submitting to the present tactics of charity. The only way to reconcile differences in regard to mooted points of responsibility between managing boards and medical staffs is to create an authoritative bureau of arbitration, as indorsed by the speaker in question and often enough advocated before. Dr. Wiggin covers this and many other essential points in his summing up of remedies. In fact, this was the central idea of the bill which passed the legislature last winter, but which failed to become a law because of the weak-kneed condition of our present governor, who was persuaded to miss the opportunity of gaining the good will and support of the medical profession by listening to the arguments of two or three gentlemen who represented merely the college interests as to clinical material. But, as we have already said, the profession is still earnest in its endeavors to right the monstrous wrong and will again be heard before the next legislature, college or no college, governor or no governor. It is simply a question of right and fair play, and we can afford to wait and have still courage to fight. The MEDICAL RECORD has always been on the side of the great majority of the profession in this matter, and is more than ever determined to do its best to bring this bitter, burning wrong within the pale of candid and fearless discussion.

THE PROGRESS OF YELLOW FEVER.

THE epidemic of yellow fever in the South begins to show signs of subsidence, owing no doubt to the favorable weather conditions which have prevailed during the past few days on the Gulf coast. The daily mean of temperature is gradually falling and the course of the disease is apparently checked somewhat by the cooler weather. A slight frost is usually encountered, according to the records of the weather bureau, some time between the 22d and 29th of this month, and when that comes we may look for a speedy termination of the epidemic. From the date when the disease prevailing at Ocean Springs was recognized to be yellow fever to Monday of this week, the total number of cases in the five places most severely afflicted by the scourge was exactly sixteen hundred. The mortality has fortunately been slight, being only about 7.5 per cent., a remarkably low figure for the disease

when occurring in communities where it does not prevail habitually.

There are at present cases in quarantine in Boston, Baltimore, and most of the important northern Atlantic ports; but of course there is no danger of the spread of yellow fever in the North at this season of the year. The disease has been prevailing for the past three months in the island of Jamaica, the latest reports, dated October 9th, giving the total number of cases in Kingston as fifty-three, with eighteen deaths. One of those who have had the disease is the newly appointed United States consul, Mr. Dent. The physicians of Kingston are not of one mind, however, concerning the nature of the disease, some calling it malignant typhoid fever. It hardly seems possible that there could be a confusion of this sort, and the suspicion is forced upon the reader of the conflicting reports that this is only an attempt to conceal the true nature of the disease. If this is the case, the physicians are scarcely acting for the good of the island, for the occurrence of yellow fever is an accident, and the disease may reasonably be expected to disappear when the cooler weather sets in, but the existence of a widespread epidemic of typhoid fever would point to a grave and probably permanent defect in the water supply.

A cable dispatch to *The Sun*, dated October 10th, states that Dr. Sanarelli, the discoverer of the bacillus of yellow fever, announces that he has discovered a curative serum. He will shortly publish the results of his experiments. This is interesting as a matter of news, but it is fortunately too late for us to profit by his discovery, even if it should be substantiated.

THE HEALTH OF THE CITY AND THE DINNER TO THE MAYOR.

Considering the present disgraceful condition of our streets, with their noisome emanations from reeking trenches and their odorous banks of obstructing dirt, it is quite amusing to learn from the daily papers that our good mayor has been the willing and grateful recipient of a congratulatory dinner from a political club. There is a grim humor about the affair which can find its full vent only in the meaningless and frothy encomiums of post-prandial oratory. Considering that all the heads of departments were present and took part in the proceedings, it was a becoming opportunity for the delectable city government to lift itself by its own breeches. There were so many pleasant things said on the score of reciprocal politeness that the finest possible opportunities were offered for balancing a pleasant joke on the point of a grave fact, thus making the dinner a grand success. Doubtless the health of the city was the merriest toast of all. We quite agree with the good intentions of the guests in avoiding disagreeable subjects, as otherwise the dinner would have missed its avowed purpose and the distinguished city official would have been deprived of the hearty indorsement of his sham and impotent policy of municipal reform.

THE BOOM FOR THE CIGARETTE.

It is reported that a committee of experts has examined all the different brands of cigarettes and has pronounced them free from all adulterations. All the specimens are declared to contain nothing but pure tobacco. So far so good; but what about the tobacco and the nicotine they contain? If no tobacco or paper was used in the construction of the cigarette, nor anything else to make it what it is, we should be still better off. At best it is the most objectionable form in which tobacco can be used, and sorely needs all the apologies that are so persistently made for it.

News of the Week.

Long Island Road's Hospital Service.—The new emergency hospital car, which has been under construction in the shops of the Long Island Railroad Company, at Morris Park, Long Island, for several weeks, has been completed and will be put into commission some time next week. The car is sixty feet in length, with sliding doors at both ends and also on either side. It is fully equipped with all the necessary modern surgical apparatus, and will be in readiness for use at all times, though it will not be used in the case of minor accidents. About one-third of the car will be used as an operating-room and the remaining space will be occupied by twenty-four cots of an improved pattern, which can be converted into stretchers. The car will be in charge of Dr. J. Frank Valentine, the surgeon-in-chief of the Long Island Railroad Company, who is also the president of the New York State Society of Railroad Surgeons.

Mr. Ernest Hart.—We regret to learn that the health of Mr. Ernest Hart, the accomplished editor of the *British Medical Journal*, has been for a long time impaired. Recently it was found necessary to amputate his leg on account of necrosis of the bones of the foot, Mr. Bryant and Mr. Mitchell Bruce performing the operation. The patient rallied well, and is reported to be now making satisfactory progress toward recovery. The many friends of Mr. Hart in this country will sympathize deeply with him in learning of this misfortune, and they will join us in the earnest hope that he may soon be restored to health and strength and may long be spared to continue the editorial labors which he has discharged so faithfully and so well, to his own credit and in the best interests of the profession in Great Britain.

A Bureau of Clinics.—It is announced that the physicians connected with the teaching institutions in Philadelphia have organized a central bureau where all information will be given inquirers concerning the work for the day in the various branches of surgery and medicine at different hospitals in the city. This is accomplished by notice to the bureau by postal card or telephone. By this means the physicians who visit the city may be able to take advantage of the clinical facilities offered by the hospitals of Philadelphia, and any one calling at the central bureau can

ascertain what medical or surgical work may be going on during that day in any one of the different hospitals.

Typhus Fever at San Francisco.—The officials of the San Francisco board of health recently discovered a case of typhus fever at St. Luke's Hospital in that city. The patient, a man, aged twenty-three years, was removed to the pesthouse.

Death from a Siphon Explosion.—A child recently died in this city from injuries received in the explosion of a siphon of carbonated water which she was carrying at the time.

Dr. D. W. Hanger, of Fishersville, Va., recently took by mistake an overdose of strophanthus, and was saved only by the exertions of Drs. Watson, Morrison, and F. M. Hanger, of Staunton. We congratulate our *confrère* on his escape.

Tapeworm and the Fair Sex.—We have received eleven communications from friends in various parts of the country who protest against the statement made by a contributor that woman alone was privileged to entertain a tænia. Each of these writers reports from one to seven cases under his own observation of tapeworm occurring in male subjects. We are forced to the conclusion that women have no monopoly of this attenuated parasite.

Texas Fever Not in Iowa.—Dr. William Horne, of Mt. Ayr, Iowa, writes that the report that Texas fever had been found among cattle in southwestern Iowa is incorrect, and that there is not a single case within four hundred miles of Mt. Ayr.

Death of Professor Roy.—Dr. Charles T. Roy, professor of pathology at the University of Cambridge, England, died October 5th. He was born in 1854, was a surgeon in the Turkish army during the Servian war, was professor superintendent of the Brown Institution, and was called to the chair of pathology at Cambridge in 1884.

State Aid for Johns Hopkins University. — The Baltimore board of trade will, it is reported, memorialize the State legislature at its approaching session, setting forth the great advantage to Baltimore in a hundred different ways of having the Johns Hopkins University there, and drawing attention to the serious loss it has suffered through the lapsing of dividends on Baltimore and Ohio stock, upon which it depended for a large part of its income. The board will ask the legislature to extend aid to the university from the public treasury.

Philadelphia County Medical Society.—At a stated meeting of the Philadelphia County Medical Society, held on September 22d, Dr. Edward Martin read a paper on "The Operative Treatment of Goitre," and exhibited a series of cases in which partial excision of the enlarged thyroid gland had been successfully performed. In one of the cases the gland became the seat of suppuration, with rupture and spontaneous cure. The majority were instances of simple goitre, although one or another exhibited symptoms of exophthalmic goitre. The results in all of the cases were eminently satisfactory, from both a surgical and a medical point of view. The operation would seem indicated when medical measures have failed or afford no promise of relief.

Milk Inspection in Philadelphia.—Acting upon a communication from a number of prominent physicians, who plead for a closer inspection of milk, contending that the depots for retailing milk, and especially the general grocery store, should be under rigorous control of the board of health, the sanitary committee of this board has adopted a resolution instructing the director of the Laboratory of Hygiene to institute in conjunction with the milk division of the board a methodical bacteriological examination of the milk supply.

Schuylkill County (Pa.) Medical Society.—At a meeting of the Schuylkill County Medical Society, held at Tamaqua, Pa., on October 5th, Dr. G. M. Hamilton, of Shenandoah, read a paper on "Burns," and Dr. B. C. Maude Coble one on "Spina Bifida."

Obituary Notes.—Dr. J. A. Mayer, of Mauch Chunk, Pa., died at Philadelphia on October 5th, from heart disease, at the age of sixty-seven years. He was a native of Germany, but had been a resident of Mauch Chunk for forty years.—Dr. Henry E. Brannin died at Blackwood, N. J., on October 4th, in consequence of an apoplectic seizure, at the age of sixty-one years. He was graduated from Jefferson Medical College in 1858, and was from 1879 attending physician to the Camden County Almshouse and Insane Asylum, taking an active part in an epidemic of typhus fever that broke out in these institutions in 1881.—Dr. J. K. Eshleman died at his farm, Glen Isle, near West Chester, Pa., on October 7th, in his eighty-eighth year. He was a graduate of Jefferson Medical College, but for many years had withdrawn from the active practice of his profession.—Dr. John A. Raub died at Philadelphia on September 29th, at the age of sixty-one years. He was graduated from the medical department of the University of Pennsylvania in 1862, engaging in the practice of medicine at Mount Bethel, Northampton County. He was at one time president of the Northampton County Medical Society. He came to Philadelphia in 1872.—Dr. P. Y. Frye, of Oyster Bay, N. Y., died at his home on October 9th, aged eighty years. He was a graduate of Dartmouth Medical School in the class of 1846.—Dr. Robert B. Bradford died at the Home of the Incurables in Washington on October 9th, aged sixty-six years. He was born in Virginia, and resided first in New York after his graduation. He early went into politics and had not practised for many years.—Dr. Jarrard K. Smith, government physician at Koloa, in the Sandwich Islands, was shot down in his doorway, on September 24th, by a native whose mother and sister Dr. Smith had declared lepers and ordered to Molokai. Dr. Smith was born on the island of Kaui. He was educated at Honolulu, but received his medical training in this city.—Dr. W. Stoeder, professor of materia medica in Amsterdam, is reported to have been frozen

to death on Mt. Ararat, during an ascent of the mountain by members of the International Geological Congress.—Dr. Munro, of Union, S. C., died at Atlanta, Ga., on October 11th. He was a graduate of the University Medical College, in this city, in the class of 1876.

Pathological Society of Philadelphia.—A stated meeting of the Pathological Society of Philadelphia was held on September 24th, the president, Dr. J. H. Musser, occupying the chair. Dr. D. Riesman exhibited a specimen of primary carcinoma of the gall bladder, with extensive metastasis or extension by contiguity to the liver. A stone was present in the gall bladder. Dr. Joseph McFarland read a paper upon "Coccidium Oviforme," exhibiting macroscopic and microscopic preparations and specimens. The disease had broken out among rabbits used for experimental purposes, and had proved fatal on a large scale. The disease is occasionally encountered in man. Dr. A. Hand, Jr., exhibited specimens from a case of tuberculosis in a child, two years old—lungs, intestines, and spleen being profoundly involved and a tuberculous tumor being present beneath the epicardium. Dr. J. P. Arnold exhibited a tumor as large as a hen's egg, arising from the dura and embedded into the median aspect of the left hemisphere. Death resulted from unrecognized pneumonia. The lungs showed, besides, evidences of tuberculosis. In addition to hemiplegia, convulsions, and loss of sight, there was optic neuritis, more pronounced on the right. Dr. M. H. Fussell exhibited button-hole narrowing of the mitral orifice.

University of Texas. — Dr. William S. Carter, demonstrator of physiology in the University of Pennsylvania, has been elected professor of physiology in the University of Texas.

College of Physicians of Philadelphia. — At a stated meeting of the College of Physicians of Philadelphia, on October 6th, Dr. A. A. Eshner read a paper entitled "A Case of Obscure Diagnosis exhibiting Hysteric Stigmata," and presented the patient. There had been present vertigo, vomiting, hiccough, disordered gait, and nystagmus, with hemihypalgesia; and marked improvement followed hypnotic suggestion. Dr. G. H. Makuen exhibited a case of imperfect voice and one of stammering cured by the employment of scientific educational methods. The first occurred in a young man of about twenty who had used the high-pitched voice of youth, and the second in a woman who had stammered badly for quite thirty years. In both the results were extremely satisfactory.

Insanity in Prussia is reported to be increasing so rapidly that the asylums are entirely inadequate to accommodate the large number of patients requiring treatment. In 1871 the total number of lunatics in Prussia was 55,063, in 1880 it had risen to 66,345, while in 1896 it had gone up to 82,850. It is interesting to note also that, while the growth of insanity is general, it is more marked among men than among women. Of 100,000 Prussian males there are 278 insane, and of a like number of women, 243.

Navy Department, Bureau of Medicine and Surgery, Washington, D. C.—Changes in the medical corps of the United States navy for the week ending October 9, 1897. October 2d.—Medical Inspector J. C. Wise, Passed Assistant Surgeon F. A. Hesler, Assistant Surgeon R. K. Smith, detached from the *Philadelphia* and ordered to the *Baltimore;* Medical Director N. L. Bates detached from the Museum of Hygiene and ordered to duty as chief of the bureau of medicine and surgery. October 5th.—Medical Director J. R. Tryon detached from the bureau of medicine and surgery and ordered to New York as general inspector of United States naval hospitals. October 6th.—Medical Inspector H. J. Babin ordered as president of the naval examining board, New York, October 9th; Medical Director C. H. White detached as president of the naval examining board, New York, October 9th, and ordered to Washington in charge of Naval Museum of Hygiene. October 8th.—Assistant Surgeon J. C. Pryor detached from the naval hospital, Mare Island, and ordered to the *Adams.*

Of Sound and Disposing Mind and Memory.—The Paris correspondent of the *Therapeutic Gazette* tells of a young poet who for some time had been accustomed to use both hashish and morphine, who recently committed suicide by means of an overdose of the latter drug. By his will he left the greater part of his fortune, amounting to $120,000, to his mistress, and $1,000 to a member of the legal profession. If, however, his will were attacked by any members of his family on account of supposed undue influence, the entire amount was to go to the latter legatee. The brother-in-law of the poet endeavored to have the will annulled, not on account of undue influence, but because of the well-known abuse of morphine which the deceased had suffered from. The court decided that inasmuch as the abuse of morphine could not be considered as in any sense doing away with the culpability of the individual in a criminal case, it could not be regarded as diminishing the responsibility of the individual in a civil cause.

Antisepsis in the Barber Shop.—A cable dispatch to the *Sun* says that the sanitary authorities of Paris have induced the prefect of police to issue stringent instructions to barbers, informing them that all metal instruments must be plunged directly after use into boiling soapy water. All combs of tortoise shell, ivory, or celluloid must be replaced as far as possible by metal, so as to be more easily cleansed and disinfected. Scissors, razors, clippers, and brushes must be heated to 100° C., or placed in a receptacle containing a prescribed chemical solution, before use. Shaving-brushes must be dipped in boiling water. Instead of powder puffs blowers must be used. Finally, hairdressers must wash their hands before passing to another customer.

Influenza in peculiarly virulent form has for some months been raging in Mero, in Asia, and alarm is felt in Russia lest another wave of the disease spread thence over the Western world.

Society Reports.

NEW YORK STATE MEDICAL ASSOCIATION.

Fourteenth Annual Meeting, Held in New York, October 12, 13, and 14, 1897.

CHARLES PHELPS, M.D., PRESIDENT.

First Day—Tuesday, October 12th.

THE meeting was called to order by the president, DR. CHARLES PHELPS, at 10:30 A.M.

Report of the Committee of Arrangements.—DR. CHARLES E. DENISON, of New York, read the report of this committee, and extended to the members a hearty welcome.

Annual Report of the Council.—It was stated that there was in the general fund in the treasury a balance of $3,510 to the credit of the association.

Cruel Treatment of Animals in Transportation.—A communication was read from the New York State Society for the Prevention of Cruelty to Animals and Children. It asked the co-operation of the association in preventing the cruelties now imposed on animals while in transit, stating that during the past year at Buffalo sixteen thousand sheep and hogs had been taken out of the cars dead, and more than eight thousand had been removed at the same place in a diseased or disabled condition; moreover, these animals were sold for public food and consumption.

Resolutions Concerning the "Hospital Grab."—Before the acceptance of the report, DR. THOS. H. MANLEY asked what action had been taken by the council on the resolutions that he had presented to them at the two preceding meetings of the association. These resolutions, it would be remembered, were in regard to the injustice done to the medical profession here by the wholesale turning out of the members of the visiting staffs of the city hospitals. The secretary explained that reference had been made to this matter in the printed volume of Transactions, and, on being pressed for a more specific answer, stated that, so far as he recollected, the council had practically refused to take any action.

Acute Catarrh of the Middle Ear as a Sequel of the Grippe.—DR. SAMUEL W. SMITH, of New York County, presented the first scientific paper, with the above title. He said that the physician should be able to recognize and treat intelligently acute inflammation of the middle ear, but it was true that the average practitioner did not do so. Ordinarily, the victim of chronic otorrhœa would state that the physician who had attended him at the time of his first attack had practically advised him to "do nothing," or, at most, syringe the ear with soap and water. One of the early and prominent symptoms was a deep-seated pain, throbbing in character, and increased by talking or any sudden expiratory act through the nostril. Recumbent posture would increase the pain. A tickling sensation was experienced in the pharyngeal organs, with dulness of hearing and tinnitus aurium in the affected ear. After a few hours the pain would extend frequently from the ear to the eye, and along the side of the head to the occipital region, over the mastoid process and down the neck. About this time the pain would be very severe, and would be associated with a rise of temperature to 101° or 103° F., and perhaps also with delirium and great constitutional disturbance. Speculum examination would show a loss of the normal line of the drumhead, and the latter would soon begin to bulge toward the meatus. In favorable cases there would be a rupture either through the drumhead into the external canal, or into the throat. Not infrequently, connective-tissue bands would connect the ossicles to the walls of the tympanum, and so give rise to a permanent impairment of hearing. If early paracentesis were performed, the disease might be cut short. It was a lamentable truth that about seventy-five per cent. of these patients, through improper treatment, lost at least a portion of their hearing. More than this, this complication of the grippe might endanger even life. Pachymeningitis and thrombosis sometimes occurred, and even embolism and metastatic abscesses might result.

Differential diagnosis: In periostitis of the osseous portion of the external canal the differential diagnosis was more difficult. In periostitis there was an itching sensation along the osseous portion of the external auditory canal; in otitis media, if these symptoms were present they were referable to the pharyngeal orifice of the Eustachian tube, and travelled along the tube to the middle ear. In periostitis, the pain gradually developed; in otitis, its onset was sudden. Again, the speculum would aid in drawing the line between the two diseases; for in periostitis the membrana tympani was rarely the seat of any special change, whereas in otitis media the drum was always changed in appearance. Exploration with a blunt probe would aid in making the diagnosis, because when the latter touched a spot which was the seat of a periostitis it would cause severe pain; this would not be observed in otitis media.

DR. LEROY J. BROOKS, of Chenango County, said that although not a specialist, he had made it a practice to do two things in these cases, viz.: (1) to Politzerize the patient two or three times a day, beginning as soon as the symptoms and signs of otitis appeared; and (2) to siphon hot saline solution into the affected ear at short intervals. It was difficult for the general practitioner in private practice to obtain permission to perform paracentesis of the drumhead. He was confident that the measures he had just recommended would often abort these troublesome, not to say serious attacks.

DR. BERNARD COHEN, of Buffalo, also favored the use of the Politzer bag, and thought it a decided advantage first to put a few drops of chloroform in the tube. This seemed to assist the dilatation of the tube, and at the same time give almost instant relief. The instillation of oils in the ear was objectionable on account of their tendency to become rancid; if such an agent must be used, it was better to use some hydrocarbon like albolene, or else to use glycerin. Although a general practitioner, he did not hesitate to perform paracentesis quite early, and it was certainly much better to do this than to run the risk of the serious complications which were liable to develop when this so-called conservative policy was adopted. He had found that ear affections did badly when quinine was given.

DR. MORRIS E. DAVIS, of New York, agreed with the last speaker regarding the inadvisability of administering quinine. In these cases complicating the grippe, the treatment should consist in a saline purge, large doses of salicylate of sodium, hot applications to the ear, and hot gargles to allay the inflammation in the throat.

DR. SMITH, in closing the discussion, said that he did not favor the use of the Politzer bag, because of the pain that it produced. He felt sure that if any physician having an occluded Eustachian tube should use this air bag upon himself, he would not be disposed to inflict this treatment upon others. In children, relief would be afforded by using a dropping-tube, and with it instilling hot water into the affected ear, the patient lying on the side with this ear uppermost. When the Eustachian tube became so occluded that the discharge was pent up and forced the drum outward, it seemed to him proper to perform paracentesis, and so prevent rupture of the drum membrane.

What Shall We Do to be Saved?—Dr. T. J. Hillis, of New York, presented a paper with this rather startling title. He read only a portion of the paper, which was intended to depict, in a graphic manner, the ruin that had been wrought by dispensary abuse. It was an allegorical presentation of the subject, and contained, among other descriptive pieces, one entitled "The Deacon's Confession." According to the story, Dr. White—better known as Deacon White—felt impelled, one evening at a religious meeting, to unburden his mind regarding the sinfulness of his career. He said that before studying medicine he had been a shrewd business man, and had carried his hard business methods even into his subsequent professional life. It was he who had plotted the establishment of the "free-to-all memorial dispensary" in order to outdo his fellow-practitioners in the vicinity. He had succeeded in gratifying his ambition, but in doing so had pauperized the community, as he expressed it: "It has been said that 'the evil that men do lives after them,' but the evil that I have done lives now." As a result of his act, the honorable and competent medical practitioners of his locality had been compelled to close their doors; their patrons had been allured to the dollar-a-month banquet, and it had proved to be the banquet of death. At first his medical brethren had fought manfully for their rights, but they had soon succumbed in the unequal struggle.

A Curious Condition of the Appendix Vermiformis as Found at Operation.—Dr. E. D. Ferguson, of Troy, read this paper, and presented a specimen. The latter he considered to be unique. It had been removed from a man, thirty-two years of age, whose previous history had been good. He had had his first attack of appendicitis in March, 1893. This attack had been a protracted one, and an abscess had opened into the bowel. In December of the same year he also had a mild attack. In December of 1896 he had another attack, but was not seen by Dr. Ferguson until last January. There were at that time much pain and fever. An ice bag was kept over the affected part, and the patient fed on albumen water. The operation was not done until February 3d. A broncho-pneumonia developed three days after the operation, and an abscess developed five or six days after the operation. It was opened, drained, and packed with iodoform gauze. After this, recovery was uneventful and complete. At the operation, many firm adhesions were encountered, and after a long search a mass was found near the iliac muscle, situated between the small intestine and the colon. This mass was found to contain the distal portion of the appendix, which had become separated by gangrene. The canal had, however, been maintained. No remnant of the mesentery could be discovered, nor was there evidence of pus or recent inflammatory exudate. The opening into the cæcum was infolded and closed, and the abdomen closed without drainage.

Amputation of the Appendix by Gangrene. — The specimen was a fine example of amputation by gangrene, and from the history it was probable that this occurred in 1893. In connection with this specimen, another case was reported. He had first seen the patient last February, but had deferred operation. Another and more severe attack occurred on September 23, 1897, and then the operation had been done within six hours of the onset of the symptoms. The appendix was greatly congested, and the mucous coat thrown into folds. At the point of separation of the two portions of the appendix was a black circular line of uniform width.

Operations for Appendicitis. — The speaker said that if all patients were to be protected from the possible contingency of an acute general septic peritonitis, we must operate in all cases, because there was no means of foreseeing the occurrence of this grave complication. The most common fault now seemed to be to minimize the risks of the operation. Some recent and trustworthy statistics placed the mortality even higher than ten per cent. It was probable that, taking all cases, eighty to ninety per cent. of patients would recover from the first attack without perforation or suppuration: of those who did not recover, eighty to ninety per cent. would have a circumscribed collection of pus, and could be relieved by a simple and comparatively safe surgical procedure; in the remainder the affection would be more serious, and a large percentage of them would perish. But to save these last, we were asked to operate in every case! Dr. Ferguson concluded that in all cases of appendicitis during the first attack the operation should not be undertaken unless suppuration or diffuse peritonitis demanded it; but in relapsing or recurring appendicitis, in which it was probable that permanent distortion of the appendix existed, we should operate.

Dr. F. H. Wiggin, of New York, thought that all cases of appendicitis should be considered as surgical after the diagnosis had once been clearly established At first, we should simply use enemata and apply cold locally, but if the symptoms were more severe after thirty-six hours the patients should be operated upon. If the pulse became more rapid, it indicated serious peritonitis and the need for operation. No case in the first attack should be subjected to operation unless there was evidence of pus. He thought the experience of good operators would justify the statement that the mortality should not exceed four per cent., unless the patients were already the victims of organic disease.

Dr. Charles Phelps, of New York, was of the opinion that the great majority were examples of simple catarrhal inflammations, and that many would recover under the use of the ice coil alone. So far as he had been able to follow the patients upon whom he had not operated, there had not been recurrence. In suppurative and gangrenous cases, of course immediate operation was demanded. Probably no operation was more often done unnecessarily than that for appendicitis, largely owing to the very general discussion of appendicitis in the lay as well as the medical press. A pulse of 120 should be looked upon as an indication of great danger. The operation should be done before this stage had been reached.

The Abuse of Medical Charity, a Critical Review of Recent Literature.—Dr. Frederick Holme Wiggin, of New York, read a paper with this title. He said that his object was not so much to present individual views as to cull from recent literature—both lay and medical—the opinions of many writers. He said that it was easy to demonstrate conclusively that, as at present administered, medical charity is demoralizing to both the recipients and the donor. Some idea of the alarming growth and extent of this evil might be gained from the carefully compiled report of Dr. Stephen Smith to the State board of charity. He showed that, during 1895, 897,971 persons applied for and received free medical treatment at 105 dispensaries in this city; that 1,418,847 free visits were made by these applicants to these dispensaries; and that 78,000 persons received free board, lodging, nursing, drugs, surgical dressings, and treatment — in other words, that more than forty-nine per cent. of all who live within our borders claimed in one year to be unable to care for themselves. This should be contrasted with another statement by Dr. Smith, to the effect that during the period from 1791, when the first dispensary had been established in New York, to about 1870, the applicants for charity bore a ratio to the total population of 1.5 per cent.

Dr. Wiggin then went on to quote from an editorial
